**FIGURE 30-2.** A–D: Gowers' sign in an 8-year-old boy with DMD that is due to pelvic girdle weakness.

Unlike many myopathic disorders, joint contractures are a major concern in DMD. Nearly all affected boys older than 13 years have contractures (4,12,13), and these contractures most commonly occur first in the ankle plantar flexors, ili-tibial bands, and hip flexors, with subsequent involvement of the knee flexors and elbow and wrist flexors. There does not appear to be a strong correlation between less than anti-gravity strength for a muscle group and the severity of joint contracture, nor for strength imbalance between antagonists across a joint (4). Clearly, lower extremity contractures become a problem after transition to a wheelchair for a significant part of the day. Natural history data suggest that progressive weakness, rather than heel-cord contractures, is associated with loss of ambulation as plantar-flexion contractures greater than 15 degrees are uncommon until after wheelchair reliance (4) (Fig. 30-3).

Scoliosis is a major clinical concern in DMD, and its prevalence is strongly related to age. Although significant curves

**FIGURE 30-3.** Brothers, ages 8 and 15, with DMD. In the older brother (**left**), note the presence of profound muscular wasting, scoliosis, and multiple joint contractures. The younger brother (**right**) demonstrates scapular retraction, increased lumbar lordosis, and stance phase plantar flexion (toe walking) to maintain a weight line posterior to the hip and anterior to the extended knee.

often coincide with transition into wheelchair mobility, there does not appear to be a cause-and-effect relationship between scoliosis and wheelchair use (4,14). Rather, factors such as the adolescent growth spurt and progressive involvement of the trunk musculature may be responsible for progression of scoliosis during the adolescent years. There is some evidence that severity of scoliosis may be predicted by the type of curve and early pulmonary function measurements (15). When the curves do not involve significant kyphosis or hyperlordosis and peak forced vital capacity (FVC) is greater than 2 L, severe progressive scoliosis appears less likely.

It is now clear that bracing does not slow the progression of spinal deformity (12,16,17). Decision making for surgical management of scoliosis is closely related to pulmonary function. Although FVC volumes increase during the first decade of life close to 100% predicted with DMD, maximal static airway pressure (both maximal inspiratory and expiratory pressures) are impaired by 5 to 10 years of age. After a plateau in the early part of the second decade, there is progressive, fairly linear decline of FVC during adolescence (4). A higher peak FVC obtained at age 10 to 12 may predict less severe restrictive lung disease and spinal deformity developing over the next few years (4). An FVC below 40% predicted may contraindicate spinal instrumentation for scoliosis because of increased perioperative mortality; however, with current improved pulmonary care this is not an absolute contraindication (18). Symptomatic respiratory failure in DMD typically manifests in later adolescence. Management of this complication is covered more in detail at a later section.

It is not surprising that cardiac function is affected in DMD, because the dystrophin protein has been shown to be present in both the myocardium and Purkinje fibers (19). Most DMD patients older than age 13 demonstrate electrocardiogram (ECG) abnormalities (4). The first abnormalities noted are Q-waves in the lateral leads, followed by elevated ST segments, poor R-wave progression, increased R/S ratio, and resting tachycardia and conduction defects (4). ECG findings have been used to predict death from cardiomyopathy and include R wave in lead V<sub>1</sub> less than 0.6 mV; R wave in lead V<sub>5</sub> less than 1.1 mV; R wave in lead V<sub>6</sub> less than 1.0 mV; abnormal T waves in leads II, III, aVF, V<sub>5</sub>, and V<sub>6</sub>; cardiac conduction defects; premature ventricular contractions; and sinus tachycardia (20). Sudden death from ventricular ectopy, a complication of the cardiomyopathy and left ventricular dysfunction, is well described in DMD (21,22). However, progressive congestive heart failure is a more frequent sequela, and some investigators estimate that 40% to 50% of DMD patients die from this complication (23,24). Cardiomyopathy is usually noted after 10 years of age and occurs in nearly all patients by age 18 (25). Cardiomyopathy is typically followed clinically with echocardiography, and the onset of systolic dysfunction is associated with a poor short-term prognosis (26). Once patients with DMD reach adolescence, regular screening with ECG, echocardiography, and Holter monitoring is prudent.

Considering the presence of a dystrophin isoform in brain tissue (27), it is not surprising that DMD patients show mildly decreased IQ scores compared with their peers and normative data (4). There may be a specific deficit with tasks requiring attention to complex verbal information, regardless of IQ (28). Mild impairments are noted on neuropsychological testing as well (4), without a specific area of strength or weakness.

Obesity from reduced physical activity is a major concern in DMD, particularly at the onset of wheelchair dependence (29,30). Since many patients are now placed on corticosteroid treatment, weight gain is the most frequently reported side effect. At later stages of the disease (ages 17 to 21), significant weight loss becomes the predominant nutritional concern (30,31). This probably results from nutritional compromise along with increased protein and calorie requirements during the later stages of DMD (32,33), partially as a result of the increased work of breathing from restrictive lung disease.

At this time, there is no curative treatment available for DMD. Oral corticosteroids have been shown to increase muscle mass, increase strength, and slow muscle deterioration. However, the mechanism of its action is still unclear. Recent studies demonstrate additional potential benefits of corticosteroids including amelioration of cardiac, pulmonary, and scoliosis complications in DMD (34–36). Research involving other pharmacagents that can increase muscle bulk and strength as well as research into the stem cell and gene therapy are ongoing.

### Becker Muscular Dystrophy

BMD is similar to DMD as an X-linked recessive disorder. It has a similar pattern of muscle weakness, but generally presents with a later onset and a slower rate of progression (Table 30-7). Like DMD, the disorder has an abnormality in the gene location (Xp21) coding for the protein dystrophin. However, in this case, dystrophin levels are usually 20% to 80% of normal, or have the presence of the protein with an abnormal molecular weight. Mutation analysis of BMD has shown that majority are “in-frame” deletions, while DMD results from “frameshift” mutations. BMD is less common than DMD, with an overall prevalence recently estimated as 24 per million (37).

Without dystrophin analysis, it may be difficult to clinically discriminate between DMD and BMD. Although age of

**FIGURE 30-4.** A 36-year-old man with BMD with pseudohypertrophy of the posterior deltoid and infraspinatus resulting in a posterior axillary depression sign.

onset typically occurs later in BMD, there is significant overlap with DMD (38). The degree of CK elevation does not discriminate between the two diseases. The most useful clinical diagnostic discriminator is the ability to ambulate into adolescence. It is unusual for a patient with BMD to be wheelchair dependent before late adolescence, whereas even DMD outliers are dependent on the wheelchair for mobility by age 16. In fact, some BMD patients may be ambulatory well into middle age and beyond. There may be two distinct patterns of progression in BMD. In the first type, age of onset averages 7.7, and most patients have difficulty climbing stairs by age 20. In the more common milder form, age of onset averages 12, and there is no problem climbing stairs at age 20. The former group also seems to have a much higher rate of ECG abnormalities (39). The percentage of normal dystrophin cannot be used to predict clinical course with any certainty in BMD (40).

Findings on examination of the BMD patient mirror DMD, although milder. The neck flexors and proximal lower limb muscles are affected early, particularly the hip and knee extensors (38). Subsequently, there is gradual involvement of the proximal upper-limb muscles (Fig. 30-4). Extensors are

**TABLE 30.7** Comparison of Clinical Features Between DMD and BMD

	Duchenne Muscular Dystrophy	Becker Muscular Dystrophy
Age of onset	Childhood < age 5	Childhood/early adolescence
Pattern of weakness	Proximal	Proximal
Wheelchair dependence	Late childhood/early adolescence	Late adolescence or later
Scoliosis	Severe and progressive	Usually mild
Cardiac involvement	Significant	Significant
Pulmonary dysfunction	Severe and progressive	Usually mild
Cognitive involvement	Frequent	Unusual

generally weaker than flexors (38). Calf enlargement occurs, and presence of Gowers' sign is indicative of the proximal muscle weakness. On standing, there is increased lumbar lordosis, and hip abductor weakness results in a waddling gait with trunk lean over the weight-bearing limb.

Contractures are not a significant early functional problem in BMD (38,39), becoming problematic only after wheelchair dependence. The joint locations for contractures are typical for one assuming the sitting posture, occurring in the hip flexors, knee flexors, and ankle plantar flexors. Significant scoliosis is much less common than DMD, and BMD patients rarely require spinal instrumentation (38,39).

One particular clinical concern in BMD is the potential for significant cardiac disease out of proportion to other manifestations of the myopathy (39,41–45). ECG abnormalities can be detected in about 75% of BMD patients (38,46). Most common abnormalities include abnormal Q-waves, right or left ventricular hypertrophy, right bundle branch block, and nonspecific T-wave changes. Echocardiography demonstrates left ventricular dilatation in 37% of BMD patients, and 63% have subnormal systolic function that is due to global cardiac hypokinesia (46). Cardiac transplantation may even be necessary in some patients (47,48). The degree of cardiac compromise may not be reflected by clinical symptoms, and these patients should be screened at regular intervals with ECG and echocardiographic studies.

Unlike DMD, significant pulmonary dysfunction is not a hallmark of BMD. FVC does not fall below the predicted level until the third to fifth decade of life. Because of relatively greater involvement of the intercostals and abdominal musculature compared with the diaphragm, maximum expiratory pressure is compromised at an earlier age than maximal inspiratory pressure (MIP), similar to DMD (38).

There are no consistent abnormalities on cognitive and neuropsychological testing in BMD other than a mild reduction in some patients (38).

### Myotonic Muscular Dystrophy (DM1 and DM2)

There are two subtypes of myotonic muscular dystrophy, DM1 and DM2 (dystrophia myotonica type 1 and type 2). Both are muscular dystrophies that share similar clinical features of myotonia and distinctive effects on other organ systems. However, DM1 and DM2 are genetically separate entities with different genes involved. DM1 is caused by abnormal expansion of the CTG trinucleotide repeats in the dystrophia myotonica protein kinase (DMPK) gene on chromosome 19q13.3, while DM2 is caused by an abnormal expansion of the CCTG repeats in the zinc finger protein 9 (ZNF9) gene on chromosome 3q21 (49–51).

Myotonic muscular dystrophy type 1 (DM1) is the most common slowly progressive dystrophy in adults, with an incidence of 1/8,000 (9), while DM2 is much less common and thought to account for only about 2% of myotonic muscular dystrophy patients. Both are multisystem disorders affecting skeletal muscle, smooth muscle, myocardium, brain, and ocular structures (Table 30-8). This may manifest clinically with

**TABLE 30.8** Rehabilitation Concerns in Myotonic Muscular Dystrophies

Progressive weakness, often in a distal > proximal distribution
Clinical myotonia, with difficulty in releasing grip
Cardiac conduction defects
Swallowing dysfunction
Cataracts
Nocturnal hypoventilation/sleep apnea

cataracts, cardiac conduction defects, endocrine abnormalities, swallowing dysfunction, and skeletal muscle weakness and myotonia.

Inheritance pattern for both DM1 and DM2 is autosomal dominant. As noted above, phenotype of DM1 results from abnormal expansion of CTG trinucleotide repeats within the DMPK gene (49,50). Normal individuals have fewer than 37 CTG repeats, whereas myotonic muscular dystrophy patients may have from 50 to several thousand repeats. The age of onset is inversely correlated with the number of repeats (49–51). With mild, late-onset myotonic muscular dystrophy, there may only be 50 to 150 repeats, whereas congenital myotonic muscular dystrophy may have greater than 1,000 repeats. The congenital form of myotonic muscular dystrophy is typically found only with DM1. The expanded region seems to further expand in subsequent generations, with increased severity of phenotype, in genetic anticipation. Currently, molecular genetic tests are commercially available for both DM1 and DM2 to determine the respective CTG or CCTG repeat expansions.

Patients with myotonic muscular dystrophy often have a characteristic facies. Long-standing myotonic muscular dystrophy is generally associated with a long, thin face, with temporal and masseter wasting. This is sometimes described as “lugubrious facies.” Ptosis can be prominent in these patients and contribute to the characteristic facies. Frontal balding at a young age is common in men.

The pattern of weakness in DM1 may be an unusual exception to the typical proximal greater than distal pattern in myopathies. The distal muscles may be affected to a greater extent, particularly early in the disease. This manifests as footdrop that is due to involvement of the ankle dorsiflexors, ankle invertors, and evertors and grip weakness from affected hand muscles (52). DM2 is different from DM1 in that proximal greater than distal distribution of weakness is noted. However, eventually, the neck, shoulder, and hip girdle muscles all become progressively weak in both DM1 and DM2. Significant contractures are unusual in myotonic muscular dystrophies, and scoliosis is usually a clinical problem only in congenital myotonic muscular dystrophy of DM1 (52).

A distinctive feature of myotonic muscular dystrophy among the dystrophies is the presence of myotonia, a state of delayed relaxation or prolonged contraction of muscle. This may be demonstrated by percussion of the thenar eminence with a reflex hammer, causing sustained flexion and adduction of the thumb. Grip myotonia is provoked by having the

patient sustain a tight grip, then suddenly attempt to relax. Delayed opening of the fingers will occur. Myotonic “crecendo-decrescendo” discharges are also easily elicited with diagnostic needle EMG, although not specific for myotonic muscular dystrophy. Weakness and myotonia may exist in different proportions in an individual patient, with functional problems often from only one or the other manifestation of myotonic muscular dystrophy.

Cardiac abnormalities are common in both DM1 and DM2. Approximately 70% to 75% of patients demonstrate ECG and echocardiographic abnormalities (53). Cardiac conduction defects are the primary concern, with prolongations of the PR interval, abnormal axis, and infranodal conduction abnormalities leading to potential cardiac morbidity and the possibility of sudden death in a small percentage (54). A cardiac pacemaker may be indicated. Regular cardiac evaluation is recommended, particularly for those patients with dyspnea, palpitations, chest pain, or other cardiac symptoms.

When myotonic muscular dystrophy manifests in infancy as congenital myotonic muscular dystrophy, involvement of the respiratory musculature may cause significant respiratory distress. In noncongenital myotonic muscular dystrophy, restrictive lung disease causes significant morbidity later in life for many patients with DM1 (52). Nocturnal hypoventilation and sleep apnea may occur, and clinicians should take a careful history to elicit symptoms common to these disorders: morning headache, frequent nightmares, excessive snoring, difficulty sleeping, and daytime somnolence.

Smooth muscle involvement most frequently manifests as difficulty swallowing and constipation, particularly in congenital myotonic muscular dystrophy. However, videofluoroscopy during swallowing reveals prolonged bolus transit times in adults with myotonic muscular dystrophy, placing them at risk for aspiration (55). Although a higher incidence of frank diabetes mellitus is controversial in myotonic muscular dystrophy, insulin insensitivity is a relatively common finding. Other endocrine abnormalities including primary gonadal dysfunction with infertility and thyroid dysfunction are also seen in patients with myotonic muscular dystrophy and should be evaluated when suspected. Posterior subcapsular cataract is present in almost all DM1 and DM2 patients and requires ophthalmological follow-up with eventual cataract removal if visual acuity worsens.

Cognitive deficits are most profound in the congenital myotonic muscular dystrophy population, with a reduced IQ often in the mentally retarded range (52,56). In noncongenital DM1, there is a wide range of scores with intelligence testing (52), and there appears to be some correlation between cognitive function and the number of CTG repeats at the myotonic muscular dystrophy gene locus.

### **Facioscapulohumeral Muscular Dystrophy**

FSHD was identified as a distinctive muscular dystrophy because of the predilection for slowly progressive muscular weakness in the facial and shoulder girdle musculature. It is the second most common inherited muscular dystrophy in adult

**FIGURE 30-5.** Attempted eye closure in a 21-year-old woman with facioscapulohumeral muscular dystrophy. Eye closure is weak and facial expression reduced.

population with a prevalence estimate of 10 to 20 per million (9). It is nearly always inherited as an autosomal dominant disorder, with the chromosomal abnormality identified at the 4q35 gene locus (57), with reduced DNA fragment size at the telomere region (58). The reduction in DNA fragment size is due to deletions of a repeat sequence called D4Z4; however, the specific mechanism of disease has not yet been elucidated. Currently, a highly specific and sensitive genetic test is commercially available for the diagnosis of FSHD.

The distinctive clinical feature of FSHD is the presence of facial weakness, primarily involving the orbicularis oris, zygomaticus, and orbicularis oculi. These manifest as difficulty with eye closure (but not ptosis) and expressionless face (Fig. 30-5). The patient will typically have difficulty burying the lashes and pursing the lips, drinking through a straw, or whistling. Onset of symptoms is typically in adolescence or early adulthood. There are no distinctive findings on muscle biopsy, with histology frequently demonstrating mild findings of atrophied fibers

**FIGURE 30-6.** Shoulder girdle appearance in a young woman with facioscapulohumeral muscular dystrophy. Shoulder abductor weakness and high-riding scapulae may give the appearance of trapezius hypertrophy.

along with hypertrophied fibers. Serum CK may be normal or only slightly elevated. Molecular genetic testing is available when the diagnosis requires confirmation.

In the shoulder girdle, the scapulae are typically displaced laterally and superiorly, resulting from combined weakness of the serratus anterior, rhomboids, latissimus dorsi, and lower trapezius (Fig. 30-6). Profound winging of the medial border of the scapula is common. Unlike most other muscular dystrophies, asymmetry of muscular involvement is common (59). Some authors feel this may be a manifestation of overwork weakness on the more affected side (60), but this is controversial. Although shoulder abductors and external rotators are typically involved, in some cases deltoid strength may be quite good if the scapula is stabilized. Elbow flexors and extensor involvement is common. In the lower extremities, the proximal musculature of the hip girdle is typically affected, often later in the disease course. However, there also appears to be a predilection for early involvement of the ankle dorsiflexors. About 20% of FSHD patients will eventually require either a power wheelchair or a scooter for mobility (61).

Coats' syndrome is an early-onset variant of FSHD associated with sensorineural hearing loss. Muscle weakness typically begins in infancy, with progressive weakness and wheelchair dependence by late second or third decade. There is also an associated progressive exudative telangiectasia of the retina, requiring early recognition to prevent permanent visual loss. Interestingly, audiometric studies may demonstrate high-frequency hearing loss in more common forms of FSHD patients as well (62–64).

Significant contractures are uncommon in FSHD (59), and spinal deformity typically presents as hyperlordosis, scoliosis, or a combination. Although hyperlordosis to compensate for hip extensor weakness may be severe in some patients, the scoliosis rarely progresses to the point of requiring surgical instrumentation.

Cardiac complications in FSHD are rare, although some studies report cardiac abnormalities including cardiac fibrosis (65) and cardiac conduction defects (66). Mild restrictive lung disease is present in nearly half of patients with the expiratory muscles affected to a greater extent than inspiratory muscles, similar to other dystrophic disorders (59). In the absence of significant bulbar or respiratory involvement, the life expectancy of FSHD patients is normal.

### Limb-Girdle Muscular Dystrophies

Before the advent of genetic testing, a group of patients commonly sharing a slowly progressive pattern of proximal greater than distal muscular weakness with either autosomal recessive (type 2) or autosomal dominant (type 1) inheritance were considered to have *limb-girdle muscular dystrophies*. Recent advances in molecular and genetic analyses have now identified a number of distinct genetic abnormalities with mutations in these patients. Currently, 17 subtypes of LGMD are recognized (67,68). Seven have autosomal dominant inheritance pattern (LGMD type 1, A to E) and ten with autosomal recessive inheritance (LGMD type 2, A to J). A detailed discussion of all subtypes of LGMD is beyond the scope of this chapter; however, the interested reader is directed to a recent review for more information (68). We still use the term limb-girdle muscular dystrophy as a general category of myopathy because of similarities in clinical presentation and progression.

It is important to keep in mind that “limb girdle weakness” is not unique to LGMDs. Other disorders such as BMD, myotonic muscular dystrophy type 2, EDMD, or late-onset spinal muscular atrophy should also be considered in the differential diagnosis. Determining the precise subtype of LGMDs is often difficult and may not be possible in majority of cases; however, a detailed symptom history, family history, mode of inheritance, and presence of associated clinical features may help narrow the differential diagnoses. At this time, genetic testing for few subtypes of LGMD is commercially available ([www.genetests.org](http://www.genetests.org)).

It is now known that some of the autosomal recessive LGMDs are associated with abnormalities in genes coding for components of the sarcoglycan complex, intimately involved

with the dystrophin protein in supporting the cytoskeletal structure of the muscle cell membrane (69). Although muscular weakness may eventually be profound, significant contractures and restrictive lung disease are unusual (70). In the United States, the LGMD 2C to F (sarcoglyconopathies) along with LGMD 2B (dysferlinopathy) and LGMD 2A (calpainopathy) are the most common limb-girdle dystrophies encountered; however, the distribution and prevalence of different subtypes of LGMD may differ around the world (68).

The cardiac involvement is rare and typically less than the dystrophinopathies such as DMD and BMD. However, depending on the LGMD subtypes (LGMD 1A to D, LGMD 2C to F, and LGMD 2I), it can be significant and warrants a close follow-up with cardiology consultation and regular ECG, echocardiography, and Holter monitoring. Respiratory involvement may also be a feature of the above subtypes of LGMD later in the disease course.

One subgroup of sarcoglycanopathy with a more rapid course is known as severe childhood autosomal recessive muscular dystrophy (SCARMD). These patients may mimic DMD early in the disease, with childhood onset and a similar pattern of weakness. However, it occurs equally in males and females and has a slower progression. Loss of ambulation generally occurs between 10 and 20 years.

### **Nondystrophic Hereditary Myopathies** **Congenital Myopathies**

The term *congenital myopathy* is used for a group of heterogeneous autosomal recessive disorders that typically present as hypotonia in infancy, can clearly be localized to muscle, and have weakness that is nonprogressive or slowly progressive. Frequently, there are delayed motor milestones in early childhood. Mental retardation may be profound in some syndromes. The weakness is usually in a proximal hip and shoulder girdle pattern. Because there is no progressive loss of muscle fibers, these disorders are not generally classified as dystrophic. The diagnosis for each specific disorder is based on histologic and electron microscopic muscle biopsy findings. Examples include central core myopathy, nemaline myopathy, and myotubular (centronuclear) myopathy.

### **Metabolic Myopathies**

In patients with defects in glycogen, lipid, or purine metabolism, a common primary symptom is exercise intolerance or exertional muscle pain. There may be no fixed weakness on examination. Symptoms with activity include fatigue, myalgia, and muscle stiffness. When exercise is intense, patients may note a brownish-red color of the urine from myoglobinuria that is due to frank rhabdomyolysis. In some metabolic myopathies, progressive muscle weakness may predominate over dynamic symptoms and mimic a muscular dystrophy. Examples of metabolic myopathies include acid maltase deficiency (Pompe's disease), myophosphorylase deficiency (McArdle's disease), and carnitine deficiency.

Acid maltase deficiency (glycogen storage disease type 2) is a disorder of glycogen metabolism, with defects in the

lysosomal acid maltase pathway. There are three autosomal recessive forms of acid maltase deficiency, the first presenting shortly after birth as hypotonia, with death by 2 years. The childhood-onset form is associated with delayed motor milestones and proximal weakness, with death by about age 20. In the adult variety of acid maltase deficiency, there is slow progression of proximal weakness beginning in the third or fourth decade. The clinical presentation may mimic limb-girdle dystrophy or PM. A potential treatment in the form of enzyme replacement therapy (ERT) is currently being evaluated in clinical trials. A guideline for diagnostic evaluation and management is available (71). With a potential treatment now on the horizon, it is important to consider the Pompe's disease in the differential diagnosis of a patient with limb-girdle weakness, respiratory insufficiency without significant cardiac involvement, and findings suggestive of metabolic myopathy. Pompe's disease represents one of only a handful of potentially treatable neuromuscular disorders at this time, and there is a commercially available diagnostic test.

McArdle's disease is usually inherited in an autosomal recessive pattern, more commonly in males. Because of the inability to metabolize glycogen, there is exercise intolerance, easy fatigability, and stiffness of the exercised muscles. Physical findings may be normal between episodes, although some patients develop progressive proximal weakness. There are now protocols using nonischemic forearm exercise test in the evaluation of patients for McArdle's disease (72).

Carnitine deficiency is the most common disorder of lipid metabolism. There are primary and secondary forms: The primary form has severely decreased plasma and tissue carnitine levels, and the secondary form has mild deficiency. Lack of carnitine impairs long-chain fatty acid metabolism in the mitochondria, thereby reducing energy production by the muscle cell. Oral L-carnitine supplementation may be helpful in some cases.

## **ACQUIRED MYOPATHIES**

### **Inflammatory Myopathies**

The hallmark of an inflammatory myopathy is the predominance of inflammatory cells on muscle biopsy. There are three primary types: DM, PM, and IBM. Although each is distinct, this group of myopathies is thought to involve immune-mediated processes possibly triggered by environmental factors in genetically susceptible individuals. DM and PM may be associated with disorders of the heart and lung as well as neoplasms. In addition, an inflammatory myopathy may be present as part of a multisystem disorder in other connective tissue diseases, most commonly scleroderma, systemic lupus erythematosus, mixed connective tissue disease, and Sjogren's syndrome. Overall, the age of onset for idiopathic inflammatory myopathies is bimodal, with peaks between 10 and 15 years of age in children and between 45 and 60 years of age in adults. Women are affected twice as often, with the exception of IBM, which is twice as common in men. It is important to diagnose

accurately and in timely fashion for both DM and PM, since treatment is available and prognosis depends on early initiation of immunotherapy.

### Dermatomyositis

Characteristic features of DM include muscle weakness that may present acutely, subacutely, or insidiously, along with a characteristic rash. This violaceous, scaling rash typically involves the eyelids and occurs with periorbital edema, termed a *heliotrope rash*. Other common locations for the rash are the dorsum of the hands, extensor surfaces of the knees and elbows, and ankles. Myalgias may or may not be present. The weakness initially involves the proximal musculature and may progress to the distal muscles. Pharyngeal muscle involvement is evident from the frequent finding of dysphagia or dysphonia. Other manifestations include cardiac dysrhythmias and cardiomyopathy, joint arthralgias, and interstitial lung disease. In adults, there appears to be an association between DM and occult carcinoma, and a judicious workup for carcinoma is advisable in newly diagnosed patients.

Childhood DM differs somewhat from the adult version because of the higher incidence of vasculitis, ectopic calcification in the subcutaneous tissues or muscle, and lipodystrophy. Corticosteroids alone are often highly effective in both inducing a remission and preventing a recurrence and can usually be gradually withdrawn. Adults with DM do not respond to corticosteroids quite so predictably, and other immunosuppressive agents are often required. It may be difficult to fully discontinue pharmacologic treatment.

### Polymyositis

The diagnosis of PM is often more difficult than DM, because no distinctive rash is present. It rarely occurs before age 20. Proximal limb and neck flexor muscle weakness presenting subacutely or insidiously should raise suspicion for PM. Myalgias are present in as many as one third of patients but are not generally the predominant symptom. CK elevation usually occurs at some point in the disease but may be normal in advanced cases with significant muscle atrophy. In general, serum CK level is a reasonable indicator of disease severity. Potential cardiac and pulmonary manifestations are similar to DM. Underlying carcinoma may less commonly occur than with DM. Treatment with corticosteroids supplemented by other immunosuppressive medications is the primary means of pharmacologic management.

### Inclusion Body Myositis

A third type of inflammatory myopathy with a different pattern of involvement and course was identified in the 1970s. It was termed *inclusion body myositis* because of the presence of both inflammatory cells and vacuolated muscle fibers with nuclear and cytoplasmic fibrillary inclusions. IBM is now recognized as the most common myopathy in patients aged more than 50 years (73). Males are affected more than females. IBM has distinctive involvement of both proximal and distal musculature.

In particular, the wrist and finger flexors are often more affected than the extensors, and the quadriceps may be affected out of proportion to other muscle groups. About one third have dysphagia, and the disease may be mistaken for amyotrophic lateral sclerosis because the age of onset is frequently after 50. IBM is relentlessly progressive in most cases, sometimes to the point of requiring a wheelchair for mobility. Unfortunately, it is not responsive to immunosuppressive medications, and treatment primarily involves appropriate assistive devices.

### Toxic Myopathies

Medications and toxins can have various effects on muscle and its function. They can either directly injure muscle cells or indirectly via electrolyte disturbances, muscle ischemia, excessive muscle activity, and immune mechanisms. The muscle effects of medications and toxins may be focal or generalized, and it can occur acutely or after prolonged exposure.

### Corticosteroid Atrophy and “Steroid Myopathy”

Although muscle weakness is an infrequent symptom of patients with endogenous hypercortisolism (Cushing’s syndrome), long-standing administration of exogenous corticosteroids is a common cause of proximal greater than distal muscular weakness and atrophy. Prednisone dosages higher than 30 mg/day increase vulnerability compared with lower dosages or an alternate-day regimen (74). The extent of weakness does not necessarily correlate with the duration of drug treatment. CK levels are generally normal or reduced, and muscle biopsy demonstrates type 2 greater than type 1 fiber atrophy. This is probably due to reduced muscle protein synthesis rather than increased catabolism. There is some evidence that resistance exercise training may help reduce or prevent steroid-induced myopathy (75).

### Medication-Associated Myopathies

The HMG-CoA reductase inhibitors have been developed as treatment for hypercholesterolemia. With initiation of these cholesterol-lowering agents, often called collectively the “-statin” medications, transient myalgia and mildly elevated CK levels can be observed. However, the symptoms rarely progress to a necrotizing myopathy. When necrotizing myopathy does occur, acute to subacute proximal weakness, prominent muscle tenderness, and significantly elevated serum CK can be seen. In severe cases, myoglobinuria can also occur. Stopping the medication typically leads to resolution of symptoms and return of serum CK to normal levels within several weeks. Other cholesterol- and lipid-lowering agents that are fibric acid derivatives may cause myopathy. Amphiphilic agents (used as antimalarial and antirheumatic medications) and antimicrotubular agents (such as colchicines and vincristine) have also been shown to cause myopathies.

### Alcohol-Related Myopathies

Alcohol-related myopathies are thought to be the most common among toxic myopathies. Muscle effects of alcohol are diverse and span from acute necrotizing myopathy with myoglobinuria to chronic atrophic myopathy. The common

symptoms of acute alcoholic myopathy are diffuse muscle cramps, myalgia, muscle swelling, and weakness. The exact mechanisms of alcohol-related myopathies are unknown at this time. However, severity of alcoholic myopathies appears to be related to a history of heavy, either acute or prolonged alcohol intake. Treatment is withdrawal of alcohol and correction of any electrolyte disturbances.

## Endocrine Myopathy

### Thyroid Disorders

Symptoms of muscle pain, cramps, or spasms are frequent in untreated hypothyroidism. However, only about one third of patients have demonstrable muscle weakness (76). In these patients, subtle proximal weakness with hyporeflexia and delayed relaxation of reflexes is evident. A PM-like syndrome with more profound proximal weakness and elevation of muscle enzymes may also occur (77). CK may be elevated 10- to 100-fold. Muscle histology is nonspecific, and the weakness resolves with appropriate thyroid hormone replacement. Thyrotoxicosis may present with symptoms of muscle weakness and proximal weakness, atrophy, and preserved or even brisk reflexes on examination. CK level is usually normal or low, and muscle biopsy may be normal or show predominant atrophy of type 2 fibers. The etiology is probably from increased catabolism of muscle tissue. Treatment of thyrotoxicosis improves the myopathy.

## Infectious Myopathy

### HIV Infection

HIV infection may be associated with an inflammatory myopathy or myositis, generally in patients with acquired immunodeficiency syndrome (AIDS). The clinical presentation is similar to idiopathic PM, with symmetric proximal weakness and elevation of serum CK. This disorder needs to be distinguished from the myotoxicity of zidovudine as well as the generalized weakness that may occur with advancing HIV infection.

## Myopathies Associated with Systemic Disease

Many major illnesses are associated with muscle compromise, not generally demonstrable by manual muscle testing but resulting in poor muscle endurance and reduced motor performance with functional tasks. This is not generally classified as a “myopathic” disorder. However, certain systemic diseases or conditions do have a particular predilection to involve muscle and may be considered myopathies.

With severe illness, often in the ICU setting, patients can develop critical illness myopathy, critical illness polyneuropathy, or a combination of these syndromes (78,79). Critical illness myopathy may develop in patients who received high doses of corticosteroids with or without neuromuscular blocking agents or who have sepsis with multiorgan system failure. Necrotizing myopathy may be associated with underlying neoplasm, especially adenocarcinoma or the gastrointestinal system or lung cancer.

Electrolyte disturbances associated with systemic illness of various causes can produce myopathy. Hypokalemia is the

most common electrolyte disturbance producing muscle weakness. This may be related to the use of diuretics or chronic diarrhea. Weakness is usually proximal, and CK elevation corresponds to the level of weakness. Frank rhabdomyolysis may be present, with muscle fiber necrosis noted on muscle biopsy. Clinical resolution occurs with correction of the hypokalemia. Other electrolyte abnormalities, which may be associated with muscle weakness, include hypocalcemia and hypercalcemia, hypophosphatemia, hyponatremia, and hypermagnesemia.

## REHABILITATION CONCERNS AND STRATEGIES IN MYOPATHIC DISORDERS

### Weakness and Resistance Training

The primary clinical manifestation of myopathies is muscle weakness. With the exception of certain inflammatory and metabolic myopathies, there is currently no effective pharmacologic management. Thus, the primary physiatriac goal is to maintain strength, function, and independence. By using appropriate bracing, gait aids, and other assistive devices, functional mobility may be prolonged. Because of the proximal predilection of weakness, coming from sit to stand, managing stairs, and completing overhead activities such as dressing are primary functional problems.

An essential tool to maintain strength in most chronic diseases is resistance exercise. This is a controversial issue in myopathies (80,81). There is not clear evidence that persons with myopathy respond to strengthening exercise in a similar fashion as the able-bodied, and significant concern about overworking weak muscles prevents widespread acceptance by clinicians. Unfortunately, probably because of caution and concern by caring providers, this population often adopts a sedentary lifestyle, resulting in a component of disuse weakness (82).

Traditional concern about overwork weakness in myopathy primarily stems from case reports and circumstantial evidence noted in individual patients (60,83,84). However, newer knowledge about the function of dystrophin and related glycoproteins does provide additional concern about overwork. These proteins appear to be essential in maintaining the cytoskeletal framework of the muscle fiber during muscle contraction (69,85). In animal models of dystrophin-deficient dystrophy, there is increased damage to muscle using eccentric contractions, which particularly stress these cytoskeletal elements (86,87). Thus, it is conceivable that intensive muscle contractions, particularly when including an eccentric component, may damage myopathic muscle to a greater extent than in the able-bodied. This is a particular concern in those diseases known to involve structural proteins of the muscle cell, such as DMD, BMD, and many of the limb-girdle syndromes. A recent study demonstrated a similar response to an acute bout of eccentric contractions in myopathic subjects and controls (88), but the effect over a longer time period is unknown.

The role of exercise differs between rapidly progressive disorders such as DMD and the more slowly progressive or static myopathies. In DMD, there is a rapid progression of strength loss when measured using qualitative (manual muscle testing) and quantitative (isokinetic dynamometry) methods (31,89). Considering this natural history, maintenance of strength would be the primary rehabilitation goal. Although hampered by methodological limitations, several investigations have demonstrated the ability to maintain or even slightly improve strength in DMD using resistance exercise (89–91). No protocol has demonstrated signs of overwork weakness. In DMD, resistance exercise activities are probably best encouraged by incorporating them into normal play and games of the child rather than a weight-lifting program (92).

In slowly progressive or static myopathies, the goal of resistance exercise is to increase strength, thereby giving the patient increased capacity to perform daily functions. A number of investigations combining patients with slowly progressive myopathies along with other peripheral neuromuscular disorders demonstrate modest benefits of strengthening exercise in slowly progressive disorders (93–97). Whether strength gains occur through direct hypertrophy of diseased muscle fibers or through reducing the effects of disuse weakness is not known. A systematic review of the literature found only two randomized, controlled trials of resistance exercise (in myotonic muscular dystrophy and FSHD) fulfilling inclusion criteria. The only conclusion drawn was that moderate-resistance strength training appeared to do no harm in these disorders, but there was insufficient evidence for benefit (98).

Therefore, unanswered questions include the appropriate regimen and whether increased strength translates into an improved ability to perform daily work tasks. There is some evidence that compared with a moderate-resistance strengthening program, a high-resistance training program offers no additional strength benefits (95,96). The moderate-resistance program included three sets of four to eight repetitions at 30% to 40% maximal strength of the knee extensors, with a similar regimen of 10% to 20% maximal strength training of the elbow flexors. No controlled investigations have demonstrated evidence of overwork weakness in muscular dystrophy.

Traditionally, patients with inflammatory myopathies were discouraged from physical activity due to fear of exacerbating muscle inflammation. Although sample sizes are small, more recent work suggests that moderate-intensity resistance exercise may improve strength and function without signs of increased muscle inflammation (99). Response to exercise may vary depending on disease activity, medications, and degree of disability. Patients with stable, chronic inflammatory myopathy may be able to tolerate more intensive strengthening regimens (ten maximal muscle contractions 3 days/week) without untoward effects (100).

### Aerobic Training

Aerobic exercise training in myopathies has received scant research attention. Involvement of the cardiac and pulmonary musculature in both dystrophic and inflammatory myopathies

may reduce cardiopulmonary fitness, compounding the effects of deconditioning. Decreased aerobic capacity compared with controls has been demonstrated in both adult patients with inflammatory myositis (101) and juvenile DM (102). Combining multiple neuromuscular diseases, several investigators have demonstrated improved oxygen uptake (103) or reduced heart rate at a submaximal workload after stationary bicycle training (104). Focusing specifically on patients with LGMD type 2I, moderate-intensity cycle endurance training was found to be safe and result in improved work capacity (105). Similarly, aerobic exercise in patients with FSHD and myotonic muscular dystrophy improved maximal oxygen uptake without signs of muscle damage (106,107). Improved oxygen uptake in subjects with inflammatory myositis was reported in two investigations combining strength and aerobic training (stationary cycling and step aerobics) not specifically designed to improve aerobic performance (108,109). There have been no randomized, controlled studies of aerobic exercise meeting Cochrane review criteria for recommendations in muscle disease (98).

Because maximal aerobic capacity is rarely the limiting factor in performing daily work tasks (110), improving muscular strength and endurance through resistance training will more likely enhance the ability to perform physical work tasks. However, an aerobic training program may help modify cardiovascular risk, because epidemiologic studies show that the physically inactive lifestyle so common in myopathic patients is associated with twice the risk of coronary artery disease in an able-bodied population (111). Swimming in warm water is a particularly useful activity to maintain aerobic capacity in myopathic patients.

### Management of Cardiac Complications

Symptomatic cardiac complications associated with myopathies are primarily seen in DMD, BMD, myotonic muscular dystrophy (DM1 and DM2), EDMD, certain LGMDs, and mitochondrial myopathies (112,113). Asymptomatic electrocardiographic abnormalities are common in the inflammatory myopathies, although significant supraventricular arrhythmias, cardiomyopathy, and congestive heart failure may occur.

In managing patients with chronic myopathies, yearly ECG screening is warranted as it is generally the first cardiac test to become abnormal (114). The dystrophin protein is normally found in the Purkinje fibers of the heart, but its absence likely contributes to the rhythm abnormalities seen in the DMD and BMD patients. When the ECG is abnormal, echocardiography is indicated, also on a yearly basis, as well as involvement of the cardiology specialist. At times, cardiac conduction abnormalities and arrhythmias associated with myopathies can be severe enough to require a pacemaker, such as in DMD and BMD, myotonic muscular dystrophy, and EDMD. Cardiomyopathy is treated in the standard fashion, using angiotensin-converting enzymes when ejection fraction is less than 35% (115), as well as digitalis and diuretics with symptomatic heart failure (116). However, special caution with kaliuretic diuretics is warranted, because hypokalemia may exacerbate weakness (117,118).

The clinician should not confuse the presence of cor pulmonale that is due to chronic respiratory failure with intrinsic cardiomyopathy. Correction of hypoxemia and respiratory failure should be performed before treating cardiomyopathy. As detailed below, this usually requires mechanical ventilatory assistance rather than provision of supplemental oxygen, which may be inappropriate and perhaps even detrimental in patients with CO<sub>2</sub> retention.

**Management of Pulmonary Complications**

Breathing disorders are the leading cause of mortality in neuromuscular diseases (119). The causes of respiratory failure include direct respiratory muscle involvement from the skeletal myopathy, alteration in respiratory mechanics, poor secretion management, infections, and occasionally a problem with central control of respiration. However, with improved pulmonary care, patients with progressive neuromuscular diseases and pulmonary system involvement are living longer. In DMD, the average life expectancy has increased from 19 to 25 years, with increasing numbers of patients in their thirties (120).

Measurements of respiratory muscle strength and function have allowed clinicians to better determine the need for ventilation and cough assistance. Serial FVC measurements have demonstrated to be highly predictive of respiratory impairment and survival. An FVC of less than 1 L has shown to be the best negative predictor of survival in DMD, with mean survival of 3.1 years and 5-year survival of approximately 8% if ventilatory support is not provided (121). Other spirometric measurements including MIP, maximal expiratory pressure (MEP), and peak cough flow are also useful in the assessment of respiratory muscle weakness. When these values decline (peak cough flow <160 L/min or MEP <45 cm H<sub>2</sub>O), they can indicate poor airway clearance function and hastened respiratory failure (122,123). Manual techniques or mechanical insufflator-exsufflators (cough-assist machines) can help in improving the airway clearance and secretion management. Intrapulmonary percussive devices and ventilators are also available to help mobilize secretions and improve pulmonary hygiene.

Progressive respiratory muscular weakness leads to restrictive lung disease manifesting as hypoventilation, hypercapnia, and ultimately respiratory failure when FVC dwindles to less than 30% predicted (124). The work of breathing is affected by the presence of pulmonary secretions, increased elastic and resistive loads, and kyphoscoliosis. In DMD, the presence of chronic hypercapnia and hypoxemia reduces central respiratory drive to these conditions, which may result in apnea during sleep and further worsening of the hypercapnia (125).

There may be a role for inspiratory muscle training through breathing against resistance in DMD. However, the current research data on the efficacy of respiratory muscle training are conflicting and no recommendation is available at this time. A study demonstrated improvement in MIP and 12-second maximal voluntary ventilation after 24 months of inspiratory muscle training (126). Others have also reported increased ventilatory strength and endurance (127–129).

**TABLE 30.9** Clinical Features Suggesting the Need for Ventilatory Support in Myopathy

Symptoms/signs
Nightmares
Morning headache
Daytime drowsiness
Generalized fatigue
Dyspnea at rest
Orthopnea
Paradoxical breathing pattern
Pulmonary function testing
Vital capacity <45–55% predicted
MIP <30% predicted
Hypercapnia

However, several investigations found no significant improvements in respiratory function (130,131). In addition, it was recently found that nitric oxide release in exercising muscle as a protective mechanism is impaired in DMD (132). It has been postulated that already dystrophic muscle may be further damaged during respiratory muscle training protocols. If instituted, one should not wait until the later stages of the disease, when respiratory muscles are already working to near their fatigue threshold (133).

Other general measures for patients with restrictive lung disease include yearly influenza vaccination and a pneumococcal vaccination unless there are contraindications. Maintenance of an optimal body weight through proper nutrition (avoiding obesity or cachexia) is crucial. A consensus statement regarding respiratory care of patients with DMD is available (134).

**Indications for Ventilatory Support**

Signs and symptoms suggesting respiratory impairment include those related to sleep-disordered breathing (nightmares, morning headache, and daytime drowsiness) as well as respiratory dysfunction (exertional dyspnea, orthopnea, generalized fatigue, and paradoxical breathing patterns) (134–136) (Table 30-9). A polysomnography with continuous CO<sub>2</sub> monitoring is helpful in determining sleep-related hypoventilation associated with myopathies. However, a nocturnal pulse oximetry in the home environment can serve as a screening tool for sleep-related oxyhemoglobin desaturation and alveolar hypoventilation when polysomnography is unavailable (137).

Several studies have examined the indices useful to predict the need for ventilatory support. Vital capacity and MIP are generally the most useful pulmonary tests. Hypercapnia generally may occur when vital capacity falls to 500 to 700 mL (135), or with a vital capacity less than 55% predicted when the MIP is less than 30% predicted (124). When monitoring a patient with progressive myopathy, general warning signs for the impending need for mechanical ventilation include severe restrictive lung disease (vital capacity <45% predicted),

respiratory muscle weakness (MIP <30% predicted), dyspnea at rest, and hypercapnia (138).

### Methods of Ventilatory Support in Myopathies

Respiratory failure often presents insidiously in chronic myopathic disorders. Noninvasive methods of managing early respiratory failure are quite effective in maintaining adequate respiratory function and usually first instituted during the nocturnal period, with demonstrated improvements in  $\text{PAO}_2$  and reduction in  $\text{PaCO}_2$  (139–143). These benefits may be carrying over into periods off the ventilator and may result in improved daytime alertness and functional ability. Investigators report that ventilator-assisted individuals with DMD have similar life satisfaction scores to the general population (144) and similar levels of health perception and social function to ventilator users with nonprogressive conditions (145).

Noninvasive positive pressure ventilation (NIPPV) may be delivered via mouthpiece with or without a lip seal, via nasal mask, or via full-face mask. In any method, the most important factor is to obtain a good seal. This method is particularly convenient for nighttime use. Nocturnal NIPPV with bilevel positive airway pressure (BiPAP) has demonstrated its efficacy in use with sleep-disordered breathing and nighttime hypoventilation in DMD (146–148). In general, BiPAP mode of ventilation rather than the continuous positive airway pressure (CPAP) is appropriate for majority of restrictive lung volume processes as seen with myopathies. Frequent monitoring for adequate mask fit and appropriate ventilator pressure level settings is necessary.

Negative pressure ventilators apply a negative pressure to the surface of the chest and abdomen, expanding the chest wall and lungs. The cuirass, or chest shell, is the prototypical negative pressure device and is occasionally used but limited by the need for a snug fit to avoid air leaks. Some patients requiring intermittent ventilatory support may be amenable to the pneumobelt, an inflatable rubber bladder strapped around the abdomen. During inflation of the device, abdominal contents are displaced upward, resulting in upward displacement of the diaphragm and passive exhalation. When the device is deflated, descent of the diaphragm then results in spontaneous inhalation. One drawback is that the patient must be seated at a greater than 30-degree angle from horizontal, making nocturnal use impractical. However, it may increase speech volume and allow time off other methods of ventilation.

Continuous invasive ventilatory support via tracheostomy should be considered when contraindications and patient aversion to noninvasive ventilation are present or when noninvasive ventilation is not feasible due to severe bulbar weakness or dysfunction. For those patients with myopathy requiring full-time ventilatory support, portable ventilators can be attached to power wheelchairs, markedly improving quality of life in the community.

### Limb Contractures and Bracing

Many chronic myopathic disorders are associated with limb contractures in later stages of the disease, usually occurring

with wheelchair dependence. Contractures may be myogenic, arthrogenic, or from soft-tissue shortening. Potentially important factors in the development of contractures in myopathies include (149) replacement of normal muscle tissue with collagen and fatty tissue, resulting in shortened muscle length; inability to obtain full range of motion of a joint; imbalance of agonist and antagonist muscle strength across a joint; static positioning in sitting; compensatory postural changes to stabilize joints for standing, most frequently seen in the equinus positioning of the ankles in DMD to keep the ground reaction force in front of the knee; and inability to obtain good muscle stretch in multijoint muscle groups, such as the hamstrings, tensor fasciae latae, and gastrocnemius.

### Prevention and Management of Contractures

In some myopathies such as DMD, contractures are inevitable with wheelchair reliance, despite aggressive stretching programs. Range-of-motion programs are most useful in ambulatory patients with mild contractures. In DMD, an early stretching program has been shown to slow the progression of contractures (150–152). A minimum of 2 to 3 hours per day standing and walking may be necessary, along with a passive stretching program to avoid contracture development (153). Proper stretching technique is essential. The stretched position should be held for a slow count of 15, and each exercise should be repeated 10 to 15 times during a session. The gastrocnemius-soleus group, hamstrings, and iliotibial bands are particularly important to stretch in younger DMD patients (154). Written instruction materials for the family effectively supplements verbal instruction. Physical modalities, such as heat to augment stretching, have not been adequately studied to recommend their use. Probably the most important component of contracture development in the weaker myopathic patient is the static position of the joint throughout each day and night.

The use of nighttime resting splints or ankle-foot orthoses to prevent plantar-flexor contractures is controversial. Some authors support their use (150), whereas others feel they are ineffective (154,155). A randomized trial in ambulatory DMD patients of stretching versus stretching and night resting splints demonstrated a 23% annual delay of heel-cord contracture in the combined group, although dropout rate was high (156). However, there is no evidence that delaying contracture development prolongs ambulation. Once contractures are present, early release of the hip flexors, iliotibial bands, and Achilles

**TABLE 30.10** Pros and Cons of Lower Extremity Bracing in DMD

Pros	Cons
Reduced contractures during adolescence	Often requires surgical release of contractures before bracing
Prolonged standing during adolescence	No prolongation of functional ambulation
Possible psychologic benefits	Risk for falls
	Need for ongoing physical therapy

tendon lengthening do not appear to have beneficial effects on strength and function in DMD (157).

### Bracing for Ambulation

Because of the proximal predilection of weakness in most myopathies, bracing for ambulation becomes much more complex and controversial than distal disorders. The greatest controversy is with DMD (Table 30-10). At the time when upright ambulation becomes difficult in DMD, hip and knee flexion contractures are usually mild (31,150), but the heel cords and iliotibial bands often require surgical release if braced ambulation is to be successful (158,159). Bracing then consists of bilateral knee-ankle-foot orthoses with solid ankles set at 90 degrees, drop-lock knee joints, and ischial weight-bearing upper-thigh components to help maintain the upright posture with reduced lumbar lordosis.

Clearly, continued standing and limited ambulating with the braces provide good stretch to the hip, knee, and ankle musculature. Heel-cord and knee flexion contractures are less pronounced at age 16 in patients who continue daily standing (154). Although reported in the literature (160), it is not clearly known if scoliosis becomes less pronounced with the use of lower extremity bracing. However, a slowing in the progression of contractures by itself does not prolong standing and ambulation, because weakness, not contractures, is primarily responsible for the transition to wheelchair reliance (149). In addition, using braces requires significant energy expenditure on the part of the patient, requires ongoing physical therapy, and increases the risk of falls. Clearly, quality of life issues require detailed discussions with the patient and family before proceeding with aggressive surgical and orthotic management in rapidly progressing muscular dystrophy. A systematic review of the effectiveness of knee-ankle-foot orthoses in DMD reports probable prolongation of standing, but not necessarily functional ambulation (161).

### Management of Spinal Deformity

Spinal deformity in neuromuscular diseases and myopathies can be very severe and progress to result in multiple problems. Severe scoliosis and pelvic obliquity can lead to pain, poor sitting balance and upright seating position, difficulty in attendant care, skin ulcers, and potential exacerbation of restrictive lung disease. Although various different myopathies can be associated with progressive spinal deformity, the most common are those that are in the hereditary myopathy category and those that are relatively more severe in disease phenotype. These include DMD, congenital muscular dystrophy (CMD), congenital myotonic muscular dystrophy, and SCARMD. Scoliosis may also be an occasional concern in facioscapulohumeral muscular dystrophy and congenital myopathies.

In DMD, scoliosis affects 75% to 90% of nonambulatory patients (31,162). The prevalence of scoliosis has shown to be closely related to age and usually becomes noticeable between the ages of 10 and 14. Although the severity of the spinal curve increases with the length of time in wheelchair, no causal relationship has been established between scoliosis progression

and wheelchair use. It is likely that both loss of ambulation and increasing spinal deformity represent disease severity and progression and are related to factors such as age, adolescent growth spurt, and weak truncal muscle. Routine screening for scoliosis with radiography before the transition to wheelchair is usually not productive. Once transitioned to wheelchair, scoliosis progression can be monitored with serial radiographs every 4 to 6 months. The reported degree of curve progression is variable (11 to 42 degrees per year) but can progress rapidly, so close follow-up is needed.

Spinal bracing in DMD does not change the natural history of the scoliosis, with continued progression despite brace usage (16,17,163). Modification of wheelchair seating system to slow the scoliosis progression has been ineffective (164). Other approaches, such as spinal exercises, manipulation, and electrical stimulation of paraspinal musculature, are also unproven. Recent studies in DMD suggest that the progression of scoliosis may be slowed with treatment with corticosteroids; however, greater side effects related to long-term corticosteroids use were also noted (34,162). At this time, the only effective treatment for progressive spinal deformity in severe myopathy remains surgical spinal instrumentation.

Indication for surgical intervention and optimal timing depends on the degree of scoliosis and cardiopulmonary status of the patient. It is generally agreed that surgical intervention should be sought when the Cobb angle is between 30 and 50 degrees (165–167). Preoperative pulmonary function testing is essential, and surgery should probably not be performed with FVC less than 30% predicted. Although a recent study demonstrated no clinically significant increase in operative and postoperative complications for those patients with FVC less than 30%, a careful preoperative risk assessment and planning as well as routine postoperative aggressive ventilatory support are stressed to minimize morbidity (168). Nocturnal pulse oximetry can provide valuable information about potential postoperative ventilation need. In those patients at risk, preoperative mask fitting and initiation of nocturnal NIPPV can improve postoperative respiratory recovery. Cardiology consultation, including preoperative ECG and echocardiography, is also important to evaluate for conduction abnormalities and cardiomyopathy. Impaired left ventricular function and cardiomyopathy are risk factors for dysrhythmias and sudden death. A potential complication of malignant hyperthermia during anesthesia is not specific to DMD. It can also occur in other myopathies and should be kept in mind for those patients undergoing anesthesia. Postoperative management after scoliosis surgery includes early involvement of therapies, mobilization out of bed when clinically stable, pain control, ventilatory support as needed, and appropriate pulmonary toilet.

Although some improvement in spinal deformity may be expected with surgical instrumentation, it is still unclear whether the procedure leads to improved or sustained pulmonary function. Progressive loss of vital capacity in DMD results from disease of the respiratory musculature, although there is probably a component from the scoliosis as well. Some studies support preserved pulmonary function and survival (17),

whereas others note no change in pulmonary decline and age at death in their DMD patients (31,169). It is important to keep in mind that the primary goals for prevention of scoliosis and corrective surgery are to provide the patients with improved sitting balance, which can help to maintain use of wheelchair, facilitate nursing care, and enhance their quality of life.

### Body Composition and Metabolic Issues

Loss of skeletal muscle, gain of excess body fat, and changes in physical activity and energy metabolism are common to both rapidly progressive and slowly progressive myopathies. Excess body weight places greater burden on already weakened skeletal muscle, reduces mobility, and may increase the work of breathing. In one study on DMD, 40% of patients were overweight (weight-for-age >90th percentile) between ages 9 and 17, 40% were underweight (weight-for-age <10th percentile) between ages 13 and 17, whereas 65% were underweight older than age 17 (31). This supports a divergence in weight in early adolescence, but a tendency toward underweight in later stages of the disease. Because of the replacement of muscle tissue by fat, at a given weight-for-age, the DMD individual will have a lower percentage of lean tissue. Although it is unclear why only certain individuals with DMD develop obesity, the weight loss in later stages of DMD may be from higher energy and protein requirements (32) with inadequate caloric intake to meet nutritional needs. Placement of a percutaneous feeding tube may be beneficial to provide rapid provision of calories and fluids, even if the patient can still swallow. Oral intake for enjoyment is still possible. Adequate nutritional intake may be a concern in slowly progressive myopathies as well. In a study of adults with nondystrophin-related muscular dystrophies, there was inadequate intake of various micronutrients and macronutrients, with significant correlations between copper, water-soluble vitamins, and strength measures (170).

The relationships between metabolism, energy expenditure, and chronic disease risk are now being considered in persons with neuromuscular diseases. Several studies have shown a lower basal metabolic rate for patients with slowly progressive myopathies (82,171,172). In a study combining patients with a number of slowly progressive neuromuscular diseases, the neuromuscular disease subjects were shown to have reduced 24-hour energy expenditure as a result of reduced physical activity and a higher percentage of fat mass than controls (82). A similar population was found to have a high risk for developing chronic diseases resulting from obesity and a sedentary lifestyle (173). Using pedometer-derived activity goals combined with dietary intervention, persons with slowly progressive neuromuscular diseases can increase physical activity and reduce caloric intake, although improved health outcomes have not yet been shown (174).

### Quality of Life/Psychosocial Issues

A survey on patients with neuromuscular diseases, including chronic myopathies, supports the notion that as a group, the quality of life of individuals with neuromuscular disease in various disease stages is not much different from that of the

**TABLE 30.11 Psychosocial Issues in Patients with Myopathy**

Lack of knowledge/information regarding the disease
Poor coordination of services
Negative attitudes of peers and health care professionals
Lack of formal education
Untreated pain

able-bodied (175). However, analysis of certain components of quality of life is of interest. Although level of impairment and disability did not predict life satisfaction, certain factors such as lack of information about the disease, poor coordination of services, negative attitudes, and decreased expectations of their potential were identified as important issues. The ability to attain independence, either through themselves or through personal care assistants, was an important key to quality of life. Support groups often serve as an excellent resource for psychological support and identifying other resources in the community. A recent study demonstrates that those patients who are single, childless, and with an earlier onset neuromuscular disease may have their quality of life impacted more by their impairments and disabilities than previously thought (176). Psychosocial issues are summarized in Table 30-11. It is important for the rehabilitation specialist to be attuned to these factors in their care of patients with myopathies, so that therapeutic interventions can be timely and effective.

Clinicians may underestimate the presence of pain in their patients with myopathies. The causes of pain are multifactorial and may be treatable, often related to joint degenerative conditions and myofascial origin rather than directly from the myopathy. A survey in slowly progressive neuromuscular diseases found that the frequency and severity of pain reported in these disorders were comparable to persons with osteoarthritis and chronic low back pain (177). Appropriate assessment and treatment of pain may significantly improve quality of life and should be part of overall psychiatric management.

In a recent survey of employment among those with neuromuscular diseases including muscular dystrophies, the major barrier to employment was lack of education (178). Level of disability and physical impairment were not critical factors. Unemployment is a particular problem in myotonic muscular dystrophy, possibly related to nonphysical factors. Although much more work needs to be done to determine ways to improve quality of life with chronic diseases such as myopathy, it is incumbent on the rehabilitation specialist to see the person beyond the disease, one in which others may view as “untreatable.” There are always interventions to be made to improve quality of life, even diseases that have no cure.

## CONCLUSION

Although great strides in genetics and molecular biology have helped us improve our understanding of many muscle

diseases, the treatment for these and most other neuromuscular diseases remains supportive rather than curative. An important component of this treatment involves appropriate and judicious use of physical activity, assistive devices, and other common physiatric interventions. Knowledge of these diseases also provides the basis of expectant management to prevent secondary complications. With this knowledge, the physician can orchestrate a rehabilitation plan matching the goals of the patient and family. With proper care, many persons with myopathy have the potential to have a reasonable quality of life.

# Osteoarthritis

## INTRODUCTION

Physiatrists, particularly those in the outpatient setting, will likely increasingly take care of patients with osteoarthritis (OA). This is due to both the growing prevalence of OA within the general population and the recognition by physiatrists, other physicians, and the general public that physiatrists possess the knowledge base and skill set to manage patients with various musculoskeletal conditions. Traditional physiatric training emphasizes function, therapeutic exercise, orthoses and assistive devices, and coordination of care with other health care professionals, especially physical therapists, occupational therapists, and social workers. Training nowadays often also includes instruction in musculoskeletal injection procedures and pain management pharmacotherapy. This combination of traditional physical medicine and rehabilitation along with interventional and pharmacologic pain management techniques places the physiatrist in a position of being able to provide the full spectrum of nonsurgical patient care.

Although the field of PM&R has not yet drafted specific management guidelines analogous to those published by the American College of Rheumatology (ACR) (1), the ACR guidelines center around many basic nonpharmacologic principles that are integral to physiatric training. Therefore, part of the nonpharmacologic treatment section of this chapter is loosely structured based upon these management strategies. The pharmacologic treatment section of this chapter is also based upon the ACR guidelines as medication recommendations were derived in part from this evidence-based medical research. Of note, the ACR guidelines are scheduled to be undergoing revision under the guidance of a subcommittee that now includes a physiatrist. These revised guidelines are scheduled to be completed during 2010.

Although physiatrists are also frequently involved in the postsurgical rehabilitation of patients who have undergone arthroplasty, this topic is covered elsewhere in this textbook.

## PATHOLOGY AND PATHOPHYSIOLOGY

OA is really a group of disorders with different etiologies but similar pathologic changes. In primary OA, it is believed that excessive loads cause failure of an otherwise normal joint (2). The changes eventually involve all of the tissues including the articular cartilage, subchondral bone, synovial tissue,

joint capsule, ligaments, and muscles that act on the joint. Histologically, small tears known as fibrillations and larger tears known as clefts both develop. These defects begin in the superficial zone of cartilage, extend into the transitional zone, and are also propagated by enzymatic breakdown of cartilage (3,4). Eventually, large areas of cartilage loss occur, thus essentially exposing the underlying subchondral bone. Other changes within the cartilage include an eventual decline in the ability of the chondrocytes to replicate, an initial increase in the water content of cartilage, a significant reduction in proteoglycan content, a reduction in the size of type II collagen fibers, shortening of the glycosaminoglycan chains, a diminution of the keratan sulfate concentration, and an increase in the proportion of chondroitin-4-sulfate consistent with immature cartilage being produced in an attempt to regenerate the lost cartilage (5). Cartilage matrix changes lead to increased matrix permeability and decreased matrix stiffness, both of which may increase tissue vulnerability to additional mechanical damage. Although the chondrocytes within the osteoarthritic joint acquire the ability to replicate and produce new chondrocytes that are very metabolically active, they produce collagen, proteoglycan, and hyaluronan (HA) that do not aggregate well and are not adequately stabilized in the extracellular matrix. Eventually, this chondrocytic repair response declines, although the exact reasons for this are poorly understood. Theories, however, include failure of the matrix to stabilize and protect the chondrocytes and a down-regulation of the chondrocytic response to anabolic cytokines.

The order of appearance of the changes in the cartilage and underlying subchondral bone is debatable. Specifically, one theory is that the subchondral bone undergoes remodeling in response to the external load applied to it due to cartilage breakdown (6). In contrast, Radin hypothesized that subchondral bone stiffening associated with remodeling in response to externally applied loads precedes and subsequently promotes cartilage loss (7). Fibrous, cartilaginous, and osseous prominences known as osteophytes eventually develop around the periphery of the joints (marginal osteophytes) but can also develop along joint capsule insertions (capsular osteophytes) or protrude from the degenerating joint surfaces (central osteophytes). Cystlike bone cavities containing myxoid, fibrous, or cartilaginous tissue eventually form within the bone. Regardless of the exact sequence of events, both cartilage degeneration and subchondral bone remodeling are found by the time the patient is symptomatic (8). Changes also occur within the synovial membrane and the synovial fluid.

Specifically, the synovial membrane may have a mild to moderate inflammatory reaction and may contain fragments of articular cartilage (9). Within the synovial fluid, pathological changes include significant alteration in synovial fluid HA, including a decrease in the concentration of normal molecular weight hyaluronate and the production of abnormal hyaluronate. The resultant decreased hyaluronate concentration is a result of both defective hyaluronate production and increased hyaluronate breakdown. In addition, there is increased water content and an increased concentration of inflammatory mediators (10). These pathological changes result in defective synovial fluid viscosity, elasticity, barrier exclusion and shielding. Exposure of synovial nociceptors perhaps explains in part the pain associated with the osteoarthritic joint.

## EPIDEMIOLOGY

More than 21% of US adults (46.4 million persons) have been reported as having “self-reported doctor-diagnosed arthritis”—for example, the patients themselves reported that a physician had previously diagnosed them with arthritis. Based on cognitive and validation studies, “self-reported doctor-diagnosed arthritis” is thought to provide the most credible estimate of overall arthritis prevalence, with acceptable sensitivity and specificity for surveillance purposes (11). As the average age of the US population increases, an estimated 67 million Americans will acquire some form of arthritis by the year 2030 (12). Among various types of arthritis, OA is the most common and affects 27 million people in the United States (13). Approximately 10% to 30% of those affected with OA have significant pain and disability (10). OA is second only to ischemic heart disease as a cause of work disability in men over age 50 (14).

Although incidence and prevalence may vary widely according to the type of epidemiologic studies, as well as by whether clinical or radiological definitions are used, the overall epidemiology of OA has been described. At least 37% (and up to 68% in some studies) of persons 60 years and older have radiographic evidence of knee OA. By contrast, 27.2% of adults 26 years and older have radiographic evidence of hand OA. Clinically, 12.1% of adults aged 60 or older have symptomatic knee OA. The prevalence of symptomatic hand OA was higher in women (9.2%) than in men (3.8%) (10,15,16).

The causes of OA are multifactorial and the risk factors may differ for each joint. Given the anticipated increase in OA prevalence, understanding the risk factors associated with OA can aid in further clarifying the disease process as well as helping to potentially delay OA progression.

## RISK FACTORS

### Genetic Factors

Multiple genes appear to confer an increased risk for OA, and the contribution of heritability and possibly genetics to the occurrence of OA varies by joint. The genetic predisposition to

OA seems to be based on a variety of physiologic vulnerabilities including changes in collagen and enzymes within cartilage, variations in cytokines or growth factor profiles in cartilage, and genes that dictate joint shape and structure (16,17).

### Age and Gender

The prevalence and incidence of OA correlates markedly with age; however, age alone does not appear to cause OA. Rather, the increase in OA with age is likely a consequence of biologic alterations that occur with the aging process. These include decreased strength, slower neurologic responses with a decline in proprioception, a decreased response of chondrocytes by growth factors, and age-related accumulation of glycation end products, which is a haphazard process impairing the function of the cartilage (18).

Younger adults also develop OA secondarily from injury and loss of biomechanical integrity.

Data show that a greater number of men present with OA before age 50; while after age 50, the condition is more common in women (19). Women experience greater severity of symptoms and report more problems with morning stiffness, joint swelling, and night pain. Women also have a higher incidence of Heberden's nodes (swelling of the distal interphalangeal [DIP] joint of the hands), a phenomenon with a familial tendency.

### Ethnicity

African Americans demonstrate a greater severity rating of knee OA than Caucasians (20). The prevalence of hip OA is higher in European Caucasians than in African-Americans. Hip OA is rare in China and in those of Chinese descent in the United States (21,22). Anatomic abnormalities that are prevalent in the United States are rare in the hips of persons of Chinese descent, which may indicate that genetic predisposition to developmental abnormalities is a factor in this ethnic variation (23). However, it may also be related to other variables including variations in body mass index (BMI), nutritional factors, and the impact of lifestyle differences and health care disparities between populations.

### Obesity

Obesity is a risk factor for the development of OA. The reason why increased body weight is associated with OA remains somewhat uncertain but may involve cartilage degeneration via excessive load bearing (24). Another mechanical factor of knee OA in overweight individuals appears to be knee alignment. In patients with varus knees, BMI appears to be related to OA severity, especially medial tibiofemoral OA (25).

In the Framingham cohort study, the BMI measured at entry into the study predicted the presence of radiographic knee OA 36 years later. It also found there was strong association between body weight and knee OA, especially in women; for women in the most overweight, relative risk was 2.07, and for men, it was 1.51 (26).

In contrast to the knee, a more modest association between body weight and bilateral hip OA has been described (27).

Various factors including abnormalities that are unrelated to obesity; adiposity lying below the hip joint, which does not contribute to loading; and distribution of body weight load more broadly may be an explanation of less clear relationship between obesity and hip OA (16).

Some studies have shown that there is an association between obesity and hand OA, with BMI being directly proportional to carpometacarpal (CMC) OA in both genders, suggesting that obesity may predispose to OA, perhaps via an inflammatory or metabolic intermediary that has not yet been identified (28–30).

### Occupation

Occupations characterized by repetitive joint loading (overuse) or high physical demands may increase the risk of developing OA. For example, farmers are at high risk for hip OA, jackhammer operators for shoulder and elbow OA, miners for knee and spine OA, and dockyard workers for knee and finger OA (16). These associations especially correlate in the setting of injury.

A systematic international review and synthesis (OASIS) states with a high degree of scientific evidence that sports and recreational activities are a risk factor for knee and hip OA and that the risk correlates with intensity and duration of exposure. But the risk is lesser than that associated with a history of trauma and overweight (31). Early diagnosis and treatment of sports-related injuries, with a goal of maintaining joint-surface integrity, should help decrease the subsequent risk of developing OA at the injured joint (32).

### Muscle Weakness

Poor quadriceps strength may predispose individuals to the development of OA (33). In a longitudinal study, women who had no radiographic evidence of OA initially but who had knee-extensor weakness were more likely to develop OA than women with no initial weakness (34). On the contrary, the progression of knee OA is more likely associated with the factors such as level of hyaluronic acid and generalized OA rather than quadriceps weakness (35,36).

## JOINT BIOMECHANICS

A deviation from normal joint biomechanics amplifies joint vulnerability leading to OA. Biomechanical alteration may include disruption or incongruity of the articular surface, dysplasia, malalignment, instability, disturbance of innervation of the joint, ligament and muscles, and inadequate muscle strength or endurance.

Knee OA with varus alignment increases the risk of medial-joint disease progression, and knee OA with valgus alignment increases the risk of lateral-joint space progression (37). In a study of varus-aligned knees, a thrust was associated with a threefold increase in the likelihood of OA progression (38).

A higher incidence of varus-valgus laxity is seen bilaterally in the knees of those with OA (both the involved and the nonarthritic knees), suggesting that laxity may predate disease

development and contribute to the disease process (39). Impaired proprioception has been seen in patients with OA compared with age-matched controls, which may also indicate that loss of proprioception precedes disease development (40).

The role of mechanical loading in the development of OA is clearer. Moderate, intermittent cyclic joint loading has been shown to be beneficial and essential to healthy joint function, but continuous compression of the cartilage suppresses metabolic activity including collagen and proteoglycan synthesis and causes tissue damage. Joint immobilization has also been shown to be detrimental, reducing cartilage thickness and proteoglycan content. In addition, intense exercise or a sudden increase in exercise, particularly in older persons, produces catabolic changes in cartilage (41,42).

## SYNOVIAL JOINTS

### Normal Anatomy/Physiology

The normal synovial joint consists of articular cartilage, subchondral bone, the synovial membrane, synovial fluid, and the joint capsule (Table 31-1). Some synovial joints also have labral tissue, interosseous ligaments, menisci, and fat pads. Most synovial joints are supported by the periarticular muscles, tendons, and ligaments. These structures are all important in ensuring proper joint function.

Normal cartilage has a surface zone, a middle zone, a deep zone, and then a zone of calcified cartilage, where the cartilage attaches to the underlying subchondral bone. In the surface zone, the collagen content is highest and the collagen fibers are oriented parallel to the joint surface. In the middle zone, collagen fibers are oriented in multiple directions, and proteoglycan content is increased. In the deep zone, collagen fibers are oriented perpendicular to the articular surface. Collagen fibers attach to the subchondral bone after a transition through the zone of calcified cartilage (43).

The articular cartilage has several functions including friction reduction, shock absorption, and the spread and transmission of weight loads to the underlying bone. Articular cartilage is composed of an extracellular matrix and chondrocytes. Under normal circumstances, there is a balance of repair and degradation of the cartilage. In OA, this balance is disrupted resulting in altered matrix and chondrocyte. Cartilage nutrition is maintained by diffusion of nutrients from the synovial fluid and facilitated imbibition (the process by which cartilage absorbs synovial fluid in response to sequential loading and unloading).

The subchondral bone also plays a role in normal joint protection as a shock absorber. The interdigitation of the cartilage and bone between the deepest layer of cartilage and the subchondral bone plate (cortical end plate) serves to transform shear forces into tensile and compressive stresses. Subchondral bone can attenuate about 30% of the loads through the joint, whereas articular cartilage attenuates only 1% to 3% of load forces (32,44). In addition to its shock-absorbing function, the subchondral bone plays a supportive role in maintaining

**TABLE 31.1** Components of Normal Synovial Joints

the joint environment. The subchondral bone contains not only bone marrow and trabecular bone but also end arteries and veins. The subchondral bone has marked porosity, with vessels penetrating the calcified cartilage zone. These help provide nutrients to the cartilage and facilitate the removal of metabolic waste products. The perfusion of these vessels accounts for more than 50% of the glucose, oxygen, and water requirements of the cartilage (44). The underlying bone also undergoes turnover as per Wolff's law that states that the bone remodels in response to externally applied forces. Thus, loads applied to the joint also help the subchondral bone to remain metabolically active.

The synovial membrane is another structure that provides joint protection. The synovial membrane is normally 1- to 2-cell layers thick. The cells themselves are known as synoviocytes and are responsible for the formation of synovial fluid via plasma ultrafiltration and production of hyaluronate specifically by type B synoviocytes. The synovial fluid undergoes the normal process of turnover, as it is removed from the joint via diffusion into the surrounding lymphatics and capillaries. Synovial fluid provides nutrient support to the periarticular cartilage and acts as either a "joint lubricant" or a "shock absorber" depending upon the load imposed upon the joint. This differential action is known as viscoelasticity and can be understood by the rate of change

of an externally applied load. Specifically, under conditions of a slowly changing load, such as slow range of motion (ROM) of the joint, the synovial fluid molecules line up so as to act as a viscous liquid (aka joint lubricant) and dissipate the externally applied energy as heat. By contrast, under high load conditions, such as stepping off of a curb, the molecules within the synovial fluid act as an elastic liquid by absorbing the externally applied energy. Another function of synovial fluid is referred to as barrier exclusion by which the movement of inflammatory cells (e.g., neutrophils) and molecular debris (e.g., fragmented cartilage known as "joint mice") within the joint is limited due to the overlap of the large molecular weight hyaluronate molecules. Finally, shielding effects refer to the coating of articular nociceptors, thereby helping to prevent pain receptor binding by inflammatory mediators (e.g., prostaglandins and bradykinins), and the coating of synoviocytes, thereby decreasing synovial membrane permeability.

The surrounding joint capsule is composed of dense connective tissue containing collagen bundles and some elastic fibers. The capsule encloses the joint and provides stability and limits ROM. The periarticular structures include the surrounding muscles and their tendinous insertions onto the joint. The muscles and tendons function to move the joint and are also theorized to protect the joint by providing support.

Overall, the joint is protected by several different tissues that serve as shock absorbers including articular cartilage, subchondral bone, synovial fluid, and the periarticular muscles/tendinous insertions. Since articular cartilage is only 1 to 2 mm thick in most regions, it is too thin to serve as the sole shock absorber. A defect, therefore, in any of the adjunctive shock absorbers contributes to degeneration of the joint, as is discussed below.

## INTRODUCTION TO NONPHARMACOLOGIC TREATMENT

A significant amount of research has been performed on nonpharmacologic treatment interventions for OA. Several of these have been validated by prospective studies and are part of the updated 2000 ACR guidelines for the medical management of hip and knee OA (1). The following 12 key nonpharmacological modalities appear in the guidelines: patient education, self-management, social support, weight loss, aerobic exercise, physical therapy (PT) ROM exercises, muscle-strengthening exercises, assistive devices for ambulation, patellar taping, appropriate footwear, lateral wedged insoles, and occupational therapy (OT) (Table 31-2).

There is relatively good evidence to support the efficacy of nonpharmacologic interventions. Unfortunately, compliance with one of the most effective interventions, therapeutic exercise is often poor as has been demonstrated in the elderly (45). Other patients might not be eligible to be enrolled in a structured therapeutic exercise program due for instance to insurance-related restrictions. In other cases, a patient might

not be willing to undergo therapeutic exercise due to a previous unsuccessful attempt at PT. In these circumstances, it becomes important for the physiatrist to distinguish a true nonresponder from a patient who did not actually receive a valid attempt at PT.

The following sections on nonpharmacologic treatment should help convince the reader that the physiatrist is in an excellent position to direct this aspect of management as it incorporates many of the educational, exercise, orthotic, and functional aspects of physiatric training.

## Patient Education and the Arthritis Foundation Overview

Despite the link between OA and high disability rates in the United States, the cost-effective interventions such as patient education to reduce the burden of OA are currently underused and often go unnoticed. Thankfully, one national voluntary health agency champions the cause for this population. The Arthritis Foundation is the largest private, not-for-profit contributor to arthritis research in the world, funding more than \$380 million in research grants since 1948. The Arthritis Foundation's overall mission is to improve lives through leadership in the prevention, control, and cure of arthritis and related diseases. In this capacity, it has been particularly active in the area of patient education and in the delivery of community-based exercise programs (46). During its 60-year history, the foundation has grown into over 150 chapters and service points nationwide to provide community-based programs, to fundraise, and to act as the primary vehicle to inform and empower the millions of Americans with arthritis. The foundation emphasizes education for the public, patients, and their caregivers. By focusing on how individuals may

take control over the debilitating aspects of the disease, this volunteer-driven organization supplemented by dedicated staff to provide professional expertise and support for volunteer efforts helps individuals with arthritis improve quality of life through its many community-based, educational programs and activities. Outreach is provided through telephone and e-mail information services as well as the foundation's internet site, [www.arthritis.org](http://www.arthritis.org), which serves as an outstanding resource for online information and support. Professional education directives also benefit health care providers to better diagnose and treat patients with arthritis. Publications, for both professional and consumer groups, continue to provide accurate and sound health information to record numbers.

### Rationale for Educational Interventions

OA often produces pain, weakness, and decreased physical function, thus negatively influencing quality of life. Psychological and socioeconomic variables influence the pain experience of OA; for example, depression may affect a patient's belief about his or her ability to cope with OA pain. High levels of anxiety, manifested by persistent attempts to avoid knee pain, may lead to loss of muscle bulk, generalized deconditioning, and subsequently a loss of confidence. With avoidance of movement, a chronic cycle of inactivity, muscle atrophy, and weakness produces further pain and inactivity. Eventually, a vicious cycle develops and perpetuates, often with a concomitant decline in function.

Since psychosocial and physical factors explain some of the pain and functional variability of persons with OA, interventions must address either or both of these domains. In a study of 69 hospital-based outpatients, pain severity, obesity, and helplessness were the most important determinants of disability (47). Patient education is one of the interventions that has demonstrated a reduction in pain and enhanced function despite continued structural pathology.

A tenet of all health care management is that the client/patient is an integral member of the team. By acquiring knowledge about the disease and the options available, an individual can best manage the implications of an arthritis diagnosis. Patient education as a planned, organized set of learning experiences designed to facilitate voluntary adoption of behaviors or beliefs conducive to health empowers the patient with new information, skills, beliefs, and attitudes to best influence health status, quality of life, and possibly health care utilization. Self-management strategies and self-efficacy, the belief that one is capable of successfully executing the behavior required to produce a certain outcome, intermingle into a framework for the adoption of the new knowledge and behaviors and strengthen the individual's confidence that he or she can perform these new actions.

### Educational Interventions

To affect behavior changes, self-help educational programs use five major strategies: contracting, feedback, modeling, reinterpreting physiological symptoms, and persuasion. The Arthritis Self-Help Program developed at the Stanford Arthritis Center

incorporates these educational principles to instruct course members about pain, fatigue, and stress management; development of an individualized exercise program; purposes and effective use of medications; identification of coping strategies; and forming a partnership with the health care team. Past participants have experienced such benefits as increased knowledge about their arthritis, increased frequency of exercise and relaxation, increased self-confidence, decreased depression, decreased pain, and decreased physician visits.

Studies have also looked at the effects of patient education combined with strengthening exercises. Persons with knee OA, who participated in an 8-week walking and education program, reported less pain and medications than controls (48). In a similar study, after the 8-week intervention, persons with knee OA had an increase of 15% in distance walked during the timed 6-minute walk test, with a concomitant increase in stride lengths at both normal and fast speeds (49). The Arthritis Foundation's research-based Walk with Ease program motivates individuals to increase their exercise levels through development of a solo or group walking programs in a safe and effective manner. Participants report such benefits as increased physical activity, increased walking distance and speed, decreased pain, and decreased depression. This program is beneficial for the participant with OA who is apprehensive about performing exercise. The curriculum empowers the individual to take the first step toward a regular physical activity program and the adoption of a healthy behavior.

For those wishing to engage in moderate physical activity, they may join one of the foundation's three Life Improvement Series Exercise programs. These evidence-based programs include the Arthritis Foundation Aquatic Program (AFAP) (to be discussed later in this chapter), the Arthritis Foundation Exercise Program (AFEP), and the new Arthritis Foundation Tai Chi Program. The latter two programs can be performed either in sitting or in standing and offer adults with arthritis options to increase physical activity while minimizing the stresses to their joints. The AFEP, formally known as people with arthritis can exercise (PACE), has been given at community centers around the country for over 20 years. This program consists of patient education infused with gentle exercise and activities that help to improve flexibility, strength, endurance, and function. Evidence shows that regular participation in these classes helps participants to better control the symptoms of the disease and the friendly and supportive atmosphere that can lead to improved mood and self-esteem. In a randomized control trial with 346 adults with arthritis, Callahan et al. found that if participants attend a majority of AFEP classes of an 8-week series of sessions twice a week, they may expect improvements in symptoms, self-efficacy for arthritis management, and upper and lower extremity function (50). They also noted that sustained improvement may require continued participation in the program.

In addition to flexibility and strength deficits with this disease, many adults with arthritis report difficulties with balance and walking. Tai Chi is an ancient, gentle form of exercise that emphasizes breathing and mental focus during the

performance of slow, continuous movements and postures. These techniques are thought to integrate the mind and the body resulting in a harmonious inner and outer self. Known benefits include increasing flexibility, muscle strength, fitness, balance, and cardiovascular (CV) health. The Sun Style of Tai Chi is especially suited for persons living with arthritis. This style utilizes forward or backward stepping motions, which is believed to improve mobility. When one foot moves forward or backward, the other foot follows. The higher stance places less stress on lower extremity joints. The coordinated breathing tied to motion promotes symptom relief and relaxation. Thus, the target audience for the Arthritis Foundation Tai Chi program is individuals with arthritis or related conditions characterized by diffuse muscle pain, decreased muscle strength, and fatigue. Preliminary outcome data suggest that participation results in improved lower extremity strength, balance, and reach.

### Weight Loss and OA Overview

Obesity is a growing epidemic in the United States and worldwide. It is estimated that currently 33.2% of women and 27.6% of men in the United States are overweight or obese (51). These statistics in conjunction with the apparent correlation between obesity and OA have prompted a number of studies. Multiple population-based studies have shown that increased body weight is associated with OA, especially of the knee, and that being overweight actually precedes the development of knee OA, rather than vice versa (52,53). In addition, it has been demonstrated that risk ratios for radiographic knee OA increase with weight, even in normal BMI range, and that weight loss protects against knee OA development (54).

A prospective study of 1,180 male medical students followed them over a median duration of 36 years. For each 8 kg (18 lb) heavier that men were during ages 20 to 29 years, the incidence of subsequent knee OA was substantially increased (relative risk = 1.7) but without an increased risk of hip OA. In addition, BMI at ages 20 to 29 years was more predictive of future knee OA than BMI at ages 30 to 39 or 40 to 49 years, indicating that duration of obesity may play a cumulative role (55).

Human obesity is associated with an increased risk of knee OA, specifically at the patellofemoral compartment and the medial tibiofemoral compartment, and most notably with simultaneous OA at both of these sites and in the knees bilaterally (52,56). Conversely, knee injury predisposes to knee OA that is usually unilateral, rather than bilateral (57). Body weight has a weaker association with hip OA than with knee OA (58). Interestingly, overweight patients may also be at increased risk for OA of the hand, thus affecting joints other than those intuitively considered to be weight bearing (58).

Women are two to three times more likely to develop knee OA in comparison with men and are twice as likely to suffer from knee OA bilaterally (59). A cross-sectional survey of 6,987 males and 7,689 females found that, without exception, for any given category of body weight, the risk of OA was

higher in women than in men within the same BMI category (60). It is believed that gender difference in reference to gait may play a role in this finding. In the McKean study done on 42 healthy subjects (18 men and 24 women) and 39 individuals (24 men and 15 women) afflicted by OA (59), it was found that OA women generated less torque at the knee and ankle and had decreased ROM at the knee. Meanwhile, OA men had results that were comparable to healthy men.

### Effect of Weight Loss on OA

In keeping with the theory that increased weight causes a proportionate increased risk in development of OA, studies were done to determine if losing the weight could lessen the risk. The Framingham Study showed that women with weight loss of approximately 11 lb during the 10-year period preceding the study decreased their risk of symptomatic knee OA by over 50%. Conversely, previous weight gain was associated with a slightly increased risk of subsequent knee OA (61). Thus, it appears that weight loss can be effective as a primary means of prevention against the onset of symptomatic knee OA.

Weight reduction seems to not only help prevent onset of OA, but it may also alleviate symptoms when the diagnosis of OA has already been made, especially for OA of weight-bearing joints (62,63). In one study where the participants lost an average of 100 lb over a 12- to 18-month period through gastric bypass surgery, there was a considerable improvement in pain, function, and knee ROM during stance and swing phase of walking (54). Research appears to indicate that even small amounts of weight loss may be beneficial for OA, especially for knee OA. For example, a study done in 2005 on elderly women in Denmark found that reducing BMI greater than two units over a 10-year period was associated with a 50% decreased risk in developing OA (64). Meanwhile, phentermine use as an anorectic agent in obese women with knee OA has been shown to be more effective than placebo at achieving 12 lb of weight loss and improving OA symptoms at the hips and especially at the knees (65).

While an ideal weight loss program would typically start with an appropriate exercise program and dietary modification as a first-line approach, the various health risks of obesity may justify the more aggressive treatment, for example, also using anorexic agents and surgical approaches, under close medical guidance (66). The potential short-term and long-term benefits of weight loss might outweigh the potential side effects (67). Thus, many clinicians and researchers now feel that pharmacotherapy may also be an appropriate and effective supplementary treatment, in addition to diet and exercise (68,69).

It has been demonstrated that the most effective nonpharmacologic weight loss interventions combine fat and caloric restriction, increased physical activity, behavioral reinforcement, and an extended weight maintenance program, with support from the physician and weight-loss support groups (68). These measures require a considerable commitment by the patient, and substantial weight reduction is often difficult to achieve and maintain (70).

The overall goals of weight loss include benefits not only to the patient's OA but also to the patient's general health and functional status (71). For example, in patients with knee OA, obesity is an independent risk factor for disability (72). An extensive review of clinical studies has shown that moderate weight loss (5% to 10% of baseline body weight) has clear benefits in terms of overall health (73).

There are still questions to be answered, but it appears as though weight loss can have a resounding beneficial effect only on the likelihood of developing OA, the symptoms of OA, and on the likelihood of progression of OA. This can be accomplished by a carefully monitored, comprehensive weight loss program including dietary modifications, appropriate exercise, and possibly pharmaceutical and surgical interventions.

## Physical Therapy and OA

### Background

While medications, injections, and orthotic interventions are valuable treatments discussed elsewhere within this chapter, it is important for rehabilitation specialists to also have specialized knowledge of the role that PT, particularly with respect to therapeutic exercise, can play in patients with OA. Many medical treatments are more successful at decreasing pain than they are at decreasing disability. But exercise often can target factors that lead to disability (74), and long-term benefits may include improving fitness and encouraging participation in physical activity programs that may help to reduce the risk of various comorbid conditions associated with obesity and a sedentary lifestyle (75). Such exercise programs may include stretching, strengthening, aerobic conditioning, aquatic programs, proprioceptive training, and use of joint-protection techniques. Until fairly recently, many physicians recommended against most exercises in OA patients, but the benefits of a well-planned exercise program have become increasingly clear within the medical literature (76–78). In 2005, the Ottawa Panel evaluated the strength of the scientific evidence on the efficacy of therapeutic exercise (79). They found 26 randomized clinical trials and controlled clinical trials for analysis. This resulted in 16 positive recommendations for therapeutic exercise and physical activity for pain management and improvement of physical function in this population. Exercise is now considered to be an integral component of primary prevention (preventing the occurrence of OA), secondary prevention (before OA has caused significant clinical symptoms), and tertiary prevention (after the diagnosis has been established) (80).

While exercise is believed to be essential for improving patient outcomes, unfortunately, definitive recommendations cannot be made regarding optimal exercise programs for any joint region with OA since with only a select number of high-level randomized clinical trials available. The inability to make judgments about the best possible exercise program is further compounded by the wide range of exercise interventions that appear in the literature. Clinical and research designs have incorporated programs that focus on simple local joint exercises to complex, multijoint exercise plans that also include

other modalities (81). Furthermore, contemporary research studies utilize different modes of exercise delivery, such that the exercises are taught to one individual or in a group setting programs, in a supervised clinical setting, community center, or on a home basis. The advantage of this array allows for the health care practitioner to select exercise regimens that may maximize a patient's adherence.

### Flexibility

ROM deficits are well-known sequelae of OA (76). Hip OA typically is accompanied by deficits in internal rotation, followed later by restricted abduction and flexion. Knee OA classically involves extension lag, but flexion may also be limited. The pathophysiology of ROM deficits is probably multifactorial, including articular changes within the joint as well as shortening of myotendinous structures in areas of pain and/or weakness. Joint stiffness is a common complaint of OA patients. Decreased ROM is often found not only at the OA joint but also at other joints within the same lower limb and even in the contralateral lower limb (76). When muscles are shorter than their ideal length, they are at a biomechanical disadvantage when they are required to generate force. Thus, a stretching program to address inflexibilities should probably be incorporated early in an exercise program for OA patients. ROM is also obviously important for functional activities. For example, various degrees of knee flexion are needed for mobility, for example, requiring at least 70 degrees for walking on level surfaces, 83 degrees for climbing stairs, and 93 degrees to get up from a chair. Neutral knee extension is required for all of these activities (76). Upper limb ROM deficits in OA patients are often seen in the fingers, for example, at Heberden's node at the DIP joints, with functional implications for ADLs and fine motor skills.

A flexibility program often begins with patients gently moving their joints through the readily available ROM, to prevent further loss of range. Next, stretching should be added to reverse some of the previously accrued ROM deficits. OA patients should be taught how to perform the stretching program properly, generally with slow, gentle, and sustained stretching. Sustained stretching generally involves holding the stretch for at least 20 to 40 seconds, and perhaps longer, before relaxing and then repeating the stretch. Sudden, jerky or ballistic stretching should be avoided since it may cause exacerbation of the OA.

The rehabilitation specialist should provide the OA patient with guidance as to which muscle groups should be targeted by the stretching program. For patients with OA of the hip or knee, stretching of the quadriceps, hip flexors, and hamstrings muscles is crucial (76). Of course, any specific ROM deficits that have been identified as problematic within a specific patient should be addressed when formulating the stretching program. While some patients may be able to begin a flexibility program with little hands-on instruction, many will benefit from learning proper techniques from a qualified therapist and then transitioning to a home exercise program.

## Strengthening

Muscle weakness has long been considered to be the best correlate of functional limitations in individuals with OA, especially knee OA (74). Some studies of patients with knee OA have shown that quadriceps weakness, in particular, is the single most important predictor of lower limb functional limitations. Quadriceps weakness was a stronger predictor of disability than was pain, radiographic findings, or other factors (82).

There are many potential reasons why the quadriceps muscles are important in knee OA. It was previously theorized that quadriceps weakness in patients with knee OA was due to deconditioning from disuse, perhaps secondary to the pain of the OA. But more recent studies have shown that quadriceps weakness actually seems to precede the development of knee OA, that is, apparently serving as a causative factor for knee OA rather than resultant sequelae. Explanations for this include the role of the quadriceps muscles in knee joint protection. Presumably, repeated lower limb impulse loading may contribute to the onset or progression of knee OA. Strong knee extensors can decrease the impulse loading of the lower limb by slowing the deceleration phase before heel strike (74).

Given that the quadriceps are the muscles most often associated with knee OA, it is not surprising that they are also the most well-studied muscle group within therapeutic strengthening programs for patients with knee OA (45). A recent review by Baker and McAlindon showed that despite many differences in research designs and strengthening programs, overall the vast majority of studies assessing quadriceps strengthening have found positive outcomes in reducing pain and/or disability (74).

Strengthening exercises are often classified as closed kinetic chain (where the distal aspect of the limb is against a fixed source of resistance, e.g., the foot on the floor during squatting) or open kinetic chain (where the distal part of the limb is free in space, e.g., knee extension while seated or recumbent). Open kinetic chain exercises may allow the patient to more specifically strengthen just one movement at one joint (e.g., isolated knee extension), but these exercises increase shear forces at joints, which may exacerbate OA. Conversely, closed chain exercises seem preferable because they cause less shear forces and may more closely mimic the many synergistic movements and firing patterns required for everyday functional tasks (76).

Strengthening exercises are often classified as isometric, isotonic, and isokinetic. Isometric exercises involve contraction of muscles while they are at a fixed length, such that little or no joint motion is taking place. Isometric exercises are a reasonable initial approach for strengthening in patients who cannot tolerate repetitive joint motion, for example, with painful, inflamed joints (76). Isometric contractions held for 6 seconds, performed at 70% of the maximal voluntary contraction (MVC) and repeated 5 to 10 times daily, have been shown to increase strength, but contractions greater than 50% of MVC can produce postexercise soreness (83). While isometric contractions can be learned quickly and can result in rapid strength gains, functional benefits from isometric contraction

exercises might be limited to a small range around the joint angle of training (74,76). Therefore, these are suggested to be used prior to or in conjunction with other forms of exercises (83). In a recent study that compared the functional benefits of either a dynamic exercise program or an isometric resistive program to a control group, subjects who engaged in either exercise program increased physical function and decreased knee pain more than those participants who did not exercise (84).

Isotonic exercises are often used to maximize strength (76). By definition, isotonic refers to joint movement through its ROM, against a constant weight or resistance. Isotonic work consists of concentric and eccentric contractions, depending on whether the muscle length is shortening or elongating during the contractions, respectively. Eccentric contraction is more stressful than concentric but also results in greater strength gains. For the patient with OA, strengthening exercises should be performed within a pain-free range and progress toward the outer ROM (83).

Isokinetic exercises involve constant speed of motion throughout the joint range during muscle contraction, while the amount of resistance may vary throughout the range. Isokinetic exercises are infrequently used, due to equipment requirements and uncertain correlation to functional activities. Instead, functional training has replaced isokinetics as a component of a comprehensive exercise regime.

In summary, isotonic and closed chain exercises are probably the most beneficial therapeutic exercises in OA patients, but individuals who find these too stressful may perform isometric exercises. The goal should be to progress to isotonic and functional exercises that include a combination of open and closed chain activities (74,81).

## Balance and Proprioceptive Training

If lower extremity proprioception is suboptimal, the force of impact transmitted up to the hip and knee will be increased during weight-bearing activities (76). Repetitively, such forces may promote progression of OA and the associated symptoms. Similar to strengthening exercise prescription, the best method of optimizing balance in OA patients is not fully clear. Some older studies have shown that postural stability in OA patients is improved by strength training or especially by aerobic walking programs, while other studies have found, ironically, that exercises specifically designed to improve balance had no such effect (85). More recently, Fitzgerald investigated the use of agility training and balance/perturbation training techniques for a 73-year-old woman with complaints of instability with her bilateral knee OA. After 12 sessions, the subject reported no further incidents of instability and returned to recreational walking, tennis, and golf (86).

## Joint Protection

Joint protection is one goal of exercise in a patient with OA. Flexibility, strength, and proprioception are optimized in hopes of reducing joint stresses, decreasing shock impacts to the joint, and maximizing joint movement and alignment (76).

Recently, the uses of patellofemoral taping techniques have been applied to relieve knee pain and improve reported physical function. While the taping group reported significantly less pain and improved function than those with no tape, the placebo tape group also reported benefit (86). Energy conservation techniques may help in minimizing unnecessary activities and joint stressors, so that the OA patient will be able to use his or her sometimes limited abilities to gain the most functional independence possible.

### Modalities

Various passive modalities have been used in OA patients, with varying degrees of support within the medical literature. Application of therapeutic heat, through use of hydrotherapy, hydrocollator packs, or paraffin, seems to be effective at improving myotendinous flexibility, allowing enhanced subsequent stretching or promoting relaxation leading to pain relief. Similarly, therapeutic cold is well-tolerated and highly effective analgesic modality. A recent review of the evidence indicates that two randomized studies found that ice massage or ice packs applied to the knee improved muscle strength and ROM or decreased swelling, respectively (87). Some higher-level studies support the benefits of repeated use (4 weeks or more) of high-intensity burst modes and acupuncture-like transcutaneous electrical nerve stimulation (TENS) in relieving pain and improving function in OA patients (76,86). In a meta-analysis that specifically addressed the use of TENS for knee OA, the authors concluded that the data supported its use and reported a moderate effect size of 0.45 (81). Subsequently, TENS has been recommended as the only electrophysical agent by the American Physical Therapy Association in its recent clinical practice guidelines for patients with knee pain (88). Conversely, the medical literature contains little or no support for the routine use of electrical stimulation, iontophoresis, or ultrasound in OA patients (76,89). Possible reasons for the ineffectiveness include the limited treatment length, inconsistent dosage, and uncontrolled treatment area size and mechanical frequencies (81). In general, modalities are probably most appropriate when used as a means of facilitating more active components of the exercise program, rather than as treatments given in isolation. They may also be used for short-term relief of acute exacerbations.

Manual therapy is another intervention that physical therapists employ in conjunction with exercise to treat patients with arthritis. It is a general term used to describe passive movements applied by the physical therapist and may include passive ROM, passive accessory joint motions, soft-tissue mobilization, or massage techniques (88). These techniques aim to increase joint motion or reduce joint stiffness. Deyle et al. found that subjects who received manual therapy to the hip, knee, or ankle in addition to exercise reported significant improvements in pain, 6-minute walk test, and self-reported function when compared with a control group (90).

### Compliance

Obviously, no exercise program can be expected to be beneficial if the patient is not compliant with performing the therapeutic

activities. Health care workers treating OA patients should encourage patients to be actively engaged in performing their therapeutic exercises. Barriers to compliance should be actively elicited so that obstacles can be addressed and surmounted. Some clinicians advocate patient diaries to track compliance with recommended exercises.

A recent study on compliance in OA patients found that demographic, fitness, psychosocial, and disability-related measures did not predict compliance with any consistency. The researchers found that activity during the first few months of an exercise program was the strongest predictor of longer-term exercise compliance. Results also suggested that exercise should be prescribed at least three times each week, for approximately 35-minute sessions (91). To retain these treatment benefits longer than 6 months, the findings of a systematic review indicate that moderate evidence exists for when exercise programs contain booster sessions (92). Community-based exercise classes serve as excellent adjuncts for the long-term maintenance of the benefits obtained from the therapeutic program (81).

## Lower Limb Orthotic Intervention Background

Pain relief and joint protection via structural support and realignment are principle benefits that can be realized by the OA patient from the use of orthotic devices. The institution of a lower limb orthosis is often a team effort, involving the physician, physical therapist, and the orthotist. While the physician can direct care and prescribe bracing intervention, physical therapists can also recommend bracing during the course of treatment, and the orthotist will subsequently evaluate the patient for appropriate device function, fit, and usage. After the orthosis has been issued, the physical therapist can continue to work with the patient to help ensure proper usage and short-term compliance while the physician can monitor for long-term compliance.

Lower limb OA braces are prescribed to inhibit multiplane joint mobility so as to relieve pain associated with weight bearing. As will be discussed, pain reduction is achieved by supporting the affected joint, reducing the muscular force needed to stabilize the joint, and redirecting axial loads, which lead to intra-articular bone-on-bone forces. The clinician working with the OA patient should provide proper education on brace function and application. In particular, the prescribing physician should set proper outcomes expectations by explaining to the patient that the brace will not correct current “damage to the joint,” rather it will provide support, potential pain relief, and hopefully prevent further joint injury.

Clinically, the chief complaint of a knee OA patient is often pain within the knee and/or the surrounding tissues. Unicompartmental gonarthrosis of the medial compartment is most often seen and can be attributed to the forces present during the varus moment that is present during mid-stance of normal human gait. In order to be most effective, a knee OA brace must act to decrease this varus-related compressive force.

The early history of research as it relates to knee OA and the application of an orthotic appliance to alter forces and produce

pain relief includes two main studies. Smith et al. described the emphasis of their studies as follows: “It was often possible during weight bearing for the physician to control instability of the knee by applying forces with his own hands, and in so doing relieve the associated pain. This relief can occur even though the disease is still present, a fact emphasizing the role of mechanical stress in pain production. If pain can be reduced by the proper application of forces manually, it may also be possible to relieve it with a properly designed brace” (93). In 1975, the Canadian Arthritis Research Symposium—University of British Columbia knee orthosis (CARS UBC), as described by Cousins and Foort, was designed specifically for the treatment of knee OA (94). The brace was comprised of plastic thigh and calf shells, utilized universal hinges and a telescoping tube assembly, and required a waistband for suspension.

Knee bracing for medial compartment gonarthrosis currently involves application of a three-point force system across the coronal plane of the knee joint, that is, valgus bracing that “unloads” the medial compartment. Current bracing terminology refers to this type of orthosis as an “unloading brace” (Fig. 31-1). Manufacturing trends have focused on single and double upright brace designs that are fabricated from high strength, very light weight materials.

A more current study showed that the external varus moment at the knee was reduced during initial contact and loading response phases of the gait cycle (95). The interval between 10% and 15%, or loading response, is the point of peak varus loading; therefore, a reduction in the external varus moment about the knee during this interval is felt to be important for diminishing load and subsequent pain reduction. There was, in fact, improvement in pain and function with use of the brace as

**FIGURE 31-1.** Typical knee OA unloading brace.

measured by a visual analog scale (VAS). A second study showed that the mean femorotibial angle decreased from 185.1 degrees to 183.7 degrees. In addition, isokinetic quadriceps muscle strength increased from an average of 36.8 to 42.8 Nm (96). Another study was performed during which patients were asked to walk with and without a brace, and condylar separation angles were measured under fluoroscopic guidance. Twelve out of fifteen patients demonstrated an average condylar separation angle of 2.2 degrees, while the three subjects without separation were obese (97). Lindenfeld et al. evaluated the biomechanics of an unloader brace on patients with medial compartment involvement and found that the adduction moment at the knee was altered when the brace was worn (98). This change may reduce the load transmitted through the medial compartment, resulting in less pain. Lastly, the clinical knee score and bone mineral density of the proximal tibia were assessed in an attempt to evaluate the efficacy of valgus knee bracing. The knee score improved after 3 months, and increases in bone mineral density were seen more in the lateral tibial condyle than in the medial, suggesting that the brace transmits forces across the knee joint from the medial to the lateral side (99).

A clinician should consider using a simple knee sleeve for those patients who present with mild OA-related knee pain but without any significant angular deformity. Although there is still no scientific evidence from clinical studies that highlight positive results using only a sleeve, there are many anecdotal patient accounts. Since the nonjointed sleeve provides no significant structural support to the knee, patient-reported feelings of improved stability and reduced pain are likely due to an improvement in proprioception that theoretically occurs with use of the sleeve. In 1999, a study was performed in order to measure the efficacy of a sleeve along with pharmacological treatment versus an unloader brace and medication as compared to the control group of patients who were given medication only. A significant improvement in function, in addition to disease-specific quality of life ( $p = 0.001$ ), was found in both the neoprene-sleeve and unloader brace groups as compared to the control group. The unloader brace was on average more effective than the neoprene sleeve (100).

Wedge shoe soles/insoles are additional orthotic devices that can possibly be used to counter OA-related knee joint compressive forces. Patients have reported pain relief in the medial compartment after applying a lateral wedge under the calcaneus. Sasaki and Yasuda examined the effects of using lateral heel wedges with load transducers and roentgenograms to observe the biomechanical effects (101). The variables that were under study included the ground reaction force (GRF), the tibiofemoral angle, and the tibiocalcaneal angle. Although the GRF and the tibiofemoral angle did not exhibit a change, the lower limb mechanical axis, however, approached an upright position, and the calcaneal angle corrected in the valgus direction with reference to the subtalar joint. The observed changes were believed to reduce the axial load bearing on the medial joint surface. The use of the wedged insole at a certain angle serves as a “stimulant” to the patient, because it causes an inclination of the floor to which the patient must compensate.

Patients must adapt to the wedge via changes in muscle activity and posture, ultimately modifying their standing and walking mechanics. In addition to their effects on knee pain and forces acting at the knee, other investigators have examined the effects of lateral wedged insoles on knee kinetics. In this study, three-dimensional analysis was performed on 17 subjects with and without them wearing a 5-degree lateral wedged insole. They found no significant differences in temporal and spatial parameters; joint angles at the hip, knee, and ankle; or kinetics at the hip and ankle. The external varus moment and estimated medial compartment load at the knee were reduced significantly (102). One can interpret the results to indicate that lateral wedged insoles are a potential effective component of a conservative treatment regimen for patients with mild medial compartment OA.

Viscoelastic shoe inserts presumably provide shock absorption at the knee and as such are another intervention at the foot and ankle for the treatment of painful knee OA. Walking has been linked to the generation of impulsive loading on the human locomotor system. Impulsive loading from normal gait has been associated with “damage” to some elements of the locomotor system. Specifically, bony vibratory forces during normal gait have been detected at 25 to 100 cycles/second at initial contact and are believed to lead to articular cartilage deterioration (103). The feet, menisci of the knees, intervertebral discs, and vertebral bodies are the so-called “natural shock absorbers,” as one of their functions is to absorb and dissipate the energy that acts upon the body during heel strike. Depending on gait velocity and the foot’s viscoelastic properties, the dynamic forces to which the foot is subjected during gait may be considerably higher than the body weight. Under normal physiologic conditions, the intermittent and continuous shock and load experienced during gait tends to cause a slowly progressive weakening of the natural shock absorbers and may later lead to articular cartilage degeneration and OA. Insufficient damping of incoming shock waves can overload the proximal joint and contribute to the process of joint degeneration (103,104).

Voloshin and Wosk clearly showed that viscoelastic inserts reduce the amplitude of incoming shock waves by 42%. They, therefore, can dampen overloading and in a sense possibly prolong the life of articular cartilage. Conservative treatment, using viscoelastic shoe inserts, for patients with clinical symptoms of knee OA too yielded an improvement in symptoms by 78% (103).

After medial knee compartment involvement, patellofemoral compartment involvement is the second most common site of involvement in knee OA. The principal biomechanical factor noted to cause patellofemoral joint pain is felt to be patellar maltracking. Specifically, it is believed that there is abnormal lateral patellar tracking, thus increasing lateral patellar facet contact forces (105). The purpose of orthotic intervention is to help achieve and maintain optimal patellar tracking in order to prevent abnormal compression forces and degenerative changes. Knee braces used for patellofemoral compartment OA are specifically designed to reduce patellar compression as well as to prevent excessive lateral shifting. Criteria evaluated at time of prescription are patient vocation/

avocation, likely compliance, and cost. Patellar-stabilizing braces, infra-patellar straps, and patellar taping are some of the current orthotic treatment options.

The neoprene-sleeve patellar stabilizing brace consists of a patellar cutout and force inducing buttress pads around the inferior and lateral aspects of the patella. The brace has two circumferentially wrapped rubber straps that apply dynamic tension to a crescent-shaped lateral patellar pad. Palumbo found this sleeve useful in the treatment of patients with patellofemoral arthritis (106). Cushnaghan et al. demonstrated that medial taping of the patella resulted in a 25% reduction in knee pain compared to lateral or neutral taping (107).

Although hip OA is also extremely common, there is a much smaller body of literature on orthotic intervention for this body region. This is not surprising given the practical difficulties encountered with bracing at the hip joint. Ankle OA, by contrast, is much less common than hip and knee OA. Literature pertaining to orthotic intervention for ankle OA is quite limited and largely anecdotal.

## Conclusion

The inclusion of an orthosis into the overall treatment plan should be considered for the OA patient. Patients can benefit by using a device daily, particularly during certain activities that stress the lower limb joints. The pain that is associated with the degenerative condition can be reduced or eliminated, thereby increasing the activity level. Furthermore, more invasive treatment can be delayed or potentially avoided all together as a result of the benefit of joint protection from damaging forces. The orthosis should be used as part of a comprehensive management plan, which could include simultaneous pharmacologic intervention, joint injections, and exercise prescription. Other factors that can help to maximize the chance for success include proper patient assessment, explaining treatment goals to the patient, achieving appropriate device fit, and utilizing the services of a licensed orthotist to make modifications when necessary.

## Hand and Occupational Therapy for OA patients

In addition to the many potential benefits from PT interventions, OT is generally believed but not proven to be of benefit in select patients (1).

## OT for Upper Limb OA

OA can affect a variety of upper limb structures including the shoulder girdle region, the elbow, the wrist, and the hand. OA in the shoulder region may involve the glenohumeral joint, the acromioclavicular joint, and rarely the sternoclavicular joint and nonarticular locations such as the subacromial space due to impingement of the rotator cuff tendons and/or the subacromial bursa by acromion bone spurs. Elbow region OA may be secondary to prior trauma or as a result of inflammatory joint disease or may be primary due to repetitive overuse. OA of the wrist region can occur due to prior trauma, inflammatory joint disease, prior infection (especially prior gonococcal or Lyme infection), or perhaps due to overuse. OA of the hand region

is very common and especially affects the first CMC joint, the proximal interphalangeal (PIP) joints, and the DIP joints.

Hand OA can be associated with significant pain and disability, especially in women (108). Upper limb weakness due to deconditioning from pain-related disuse and stiffness is common in OA patients. The Arthritis Hand Function Test can provide reliable, standardized measurements of strength and dexterity in adults with OA (109).

An OT program can be targeted toward the associated pain, disability, and weakness (110). Modalities, including therapeutic heat or cold, may provide pain relief, especially during an exacerbation. Adaptive equipment may include devices that empower the patient to independently perform activities such as opening jars, buttoning clothing, or holding utensils. Occupational therapists often prescribe assistive devices to assist with ADLs and train patients in their use. Although it is believed that patients with OA are frequent users of such assistive devices, there is a scarcity of scientific evidence for the prescription, provision, and use of these in OA patients (111).

Splinting may allow inflamed joints to rest, provide support to weak muscles, control ROM, and theoretically prevent deformities (110). Prefabricated or custom-made finger splints can be used to immobilize joints that are inflamed or painful, while allowing movement at adjacent joints. OA often involves the DIP and PIP joints in the form of Heberden's and Bouchard's nodes, respectively, as well as the first CMC joint. Various finger splints are available. Some of these may offload the DIP or the PIP joint, whereas a thumb spica splint can immobilize the CMC joint and the MCP joint. A CMC splint (C splint) supports the first CMC joint while allowing movement at the wrist and at the interphalangeal (IP) joint of the thumb. A systematic review of the literature found that although there was fair evidence for the effectiveness of CMC splinting to relieve pain and improve function, further study is needed (112). Patient preference regarding type of splint varied, and there was no clear evidence of the superiority of one type of splint over another. There is also some disagreement regarding whether splinting for first CMC joint OA should also extend proximal to the wrist and/or perhaps even distal to the IP joint of the thumb (110). In general, the prescribed splint should probably be the least cumbersome brace that will immobilize the necessary joints. Any extension of the splinting beyond the primary joint(s) being targeted should be pursued only if there are symptomatic or functional gains that will offset the increased splint size. Ideally, hand and finger splints should still allow reasonably good hand dexterity for functional activities, although some patients may initially find them awkward.

The strengthening component of the OT program can guide the patient in finding the right balance between avoiding disuse and avoiding excessive repetitive stress.

OT can also help address underlying ergonomic deficiencies that may be exacerbating the upper limb OA. Ergonomic modifications can be made to workstations and home environments so as to minimize any upper limb cumulative trauma disorders that may be exacerbating upper limb OA (113). Furthermore, in patients with lower limb OA, OT can address whether assistive

devices such as canes and walkers are inadvertently causing excessive loading of the upper limbs (110). Modifications of the handles and/or heights of the walking aids can minimize detrimental impact on the upper limbs and thereby allow the patient to continue using the device.

While the literature on the effect of a course of OT for hand OA patients in general is extremely sparse, one study documented a significant improvement in mean disability score in 77 patients who underwent an OT program that included hand exercises and splints (108). A 7-year prospective study found that 70% of 33 patients with first CMC OA who were awaiting surgery for this condition no longer wanted surgery after participation in a program of modalities, splints, and ADL training (114). Referral of hand OA patients to an occupational therapist should therefore be considered, especially for first CMC OA.

### OT for Lower Limb OA

Some lower limb OA patients may benefit from OT, if there are deficits in functional activities such as lower extremity dressing, bathing, and home safety. OT can provide appropriate assistive devices to help maximize the patient's independence and function for a wide variety of tasks. Items as seemingly simple as reachers, sock donners, long-handled shoe horns, or elastic shoe laces may make the difference in whether a patient with limited lower limb ROM can get dressed without additional help (110).

### Other Benefits of OT for OA

Since endurance is believed to be often impaired in OA individuals, energy conservation techniques can play an important role in maximizing functional independence. Energy conservation techniques involve shaping the patient's habits and environment so that the most function can be accomplished with the least amount of effort. The goal is not to decrease the activity level of the individual but rather to harness that activity level as efficiently as possible, to maximize independence and quality of life. Finally, an OT can help to teach the concept of joint protection techniques to the patient. Joint protection techniques include the following principles:

1. Respect pain
2. Avoid activities that hurt affected joints
3. Use appropriate assistive devices
4. Use largest and strongest joints and muscles
5. Avoid staying in one position for too long
6. Balance activity and rest
7. Avoid prolonged periods of immobility
8. Reduce excess body weight
9. Simplify, plan, and organize

### Aerobic Conditioning and Aquatic Therapy (Aquatherapy)

The final nonpharmacologic treatment guideline is aerobic conditioning exercises, especially aquatic therapy (aquatherapy) if available. In practice, although this is listed as a separate guideline, it is often incorporated as part of a formal PT program and then conducted within a long-term home exercise program. Aerobic

exercise for OA patients commonly includes a daily walking program since physical activity levels are often reduced. Using the guideline of 30 minutes of accumulated of moderate activity on most days is an excellent goal for those patients whose lifestyles are sedentary (115). In addition to the aerobic effects, walking adds some degree of joint loading, which helps the cartilage to obtain necessary synovial nutrients via imbibition. In a review of controlled trials evaluating the role of aerobic training in patients with knee OA, Baker and McAlindon concluded that aerobic exercise effectively minimizes further progression of disability (and possibly pain) in individuals with knee OA (74). They also concluded that supervised aerobic training seemed to yield better results than unsupervised training, although even home-based programs can prevent further decline over the long term. Cycling, both indoor and outdoor, is an excellent form of aerobic exercise for most people with arthritis. This low impact activity uses the large leg muscles that are often weakened due to OA (116). Mangione evaluated the effects of high-intensity and low-intensity aerobic cycling exercises in older adults with knee OA. Both forms of aerobic activity resulted in improved functional status, pain, gait, and aerobic capacity in this population.

Water is an amazing medium for patients with arthritis to wish to exercise. The increased sensory input, relaxation from warm water, and decreased joint compression often allow individuals to move with less significant pain than when on land. The hydrodynamics can support, assist, or resist movements so that the exercise program can easily be progressed. In 1983, the Arthritis Foundation and the Young Men Christian Association (YMCA) created a warm-water, community-based exercise program: The AFAP. Since its origin, the program has undergone three revisions. From 1989 to 1990, the program added an advanced “plus” level class (AFAP/AFAP PLUS) to expand the aerobic conditioning component to the basic AFAP program. A 1995 revision task force updated safety guidelines for endurance exercise, added joint-specific precautions, and supplemented the existing program with new exercises and special

activities. A subsequent modification in April 2002 added two new versions of the aquatic program: deep-water exercise and exercise for children with arthritis. The latest revision in 2008 incorporates the advances in aquatic exercise and equipment to further enhance this widely popular program.

The basic AFAP program consists of 68 ROM and muscle-strengthening exercises for each major region of the body and is performed for up to 30 to 40 minutes. The instructor may add an optional, short 5- to 10-minutes endurance segment. By contrast, the AFAP PLUS program adds 5 to 20 minutes of endurance-building activities and additional muscle-strengthening activities to the basic program. The Deep Water AFAP classes utilize floatation devices to suspend participants above the pool floor while exercising. Due to the physical properties of the aquatic environment, most people with OA are capable of performing each of these program exercises, and the ability to swim is not necessary. Participants are encouraged to contact their physicians to discuss any exercise-related precautions or contraindications prior to beginning.

Since AFAP's inception, over a thousand aquatic facilities offered the program. Even as a recreational program, participants reported physical benefits such as decreased pain and stiffness. The friendly and supportive atmosphere promotes peer interaction, helping to decrease feelings of depression and isolation. Successful pain-free participation results in new self-efficacious behaviors, and the progression of exercise tolerance and activity level may improve functional independence and improved self-esteem.

## PHARMACOTHERAPY OVERVIEW

In addition to the nonpharmacologic guidelines discussed above, pharmacologic guidelines for OA of the knee and hip have also been published by the ACR (1). An algorithm based upon these guidelines is shown in Figure 31-2. These

**FIGURE 31-2.** Basic medication algorithm for knee or hip OA.

guidelines were last updated in 2000; therefore, the overall algorithm below remains unchanged since the previous edition of this book. There have been, however, some medication changes within the various sections of the algorithm. Although the algorithm implies a step-wise progression from one medication to another based on several key questions and response to a given treatment, the algorithm is only a simplified guide. Patients certainly have unique circumstances such as previous successful or unsuccessful responses to various treatments, insurance reimbursement issues, as well as underlying medical conditions in addition to those shown in Table 31-3 that need to be taken into account when making medication decisions based upon the algorithm. For the sake of simplicity, the notion that the clinician can and at times should prescribe more than one of the above medications simultaneously is not shown in the above algorithm. This treatment strategy of medication coadministration can take advantage of the fact that analgesics from different medication classes sometimes act synergistically and therefore limit the potential for dose-related toxicity. By contrast, as the clinical scenario changes, portions of the algorithm that had previously failed or were skipped over can be retried. For example, a patient whose knee inflammation has subsided after a corticosteroid injection but was not also receiving acetaminophen should be considered as a candidate for acetaminophen particularly if the knee inflammation was situational and related to unaccustomed exertion that is no longer present. Finally, patients ideally should be receiving nonpharmacologic treatment concomitantly, as discussed above.

Certain key questions are considered in the algorithm. The first question pertains specifically to the knee and queries whether or not there is evidence of knee inflammation. If inflammation is not evident, then the initial medication of choice is acetaminophen. Acetaminophen remains a logical choice for relief of mild to moderate OA pain of the hip and knee, especially in early OA when inflammation is less likely to be present. Hip inflammation is much more difficult, if not impossible, to determine on physical exam alone due to the deep lying position of this joint. As a result, acetaminophen remains a logical choice for initial treatment of hip OA. Several studies have compared acetaminophen to NSAIDs, including ibuprofen and naproxen, for early knee OA (117,118). In these

studies, acetaminophen was found to be equally as effective as the NSAIDs but was associated with fewer side effects, making it the initial drug of choice for treatment of early knee OA pain. This evidence has since been refuted by recent meta-analyses that have found acetaminophen to be less effective than NSAIDs but more effective than placebo for relieving OA pain (119–122). Furthermore, a survey of OA and other rheumatic disease patients found that there was a considerable preference for NSAIDs compared to acetaminophen (123,124). Although acetaminophen is less effective than NSAIDs, it is also less toxic than systemic NSAIDs, and therefore, acetaminophen is the most appropriate first-line oral analgesic for the treatment of OA (125).

Acetaminophen extended release, such as Tylenol Arthritis, provides convenience of use due to its tid rather than q4-6 dosing and may increase patient compliance. The recommended dose is one to two 650-mg extended-release tablets every 8 hours rather than one to two 325-mg standard-release tablets every 4 hours. A recent randomized controlled trial concluded that acetaminophen extended release (1,300 mg tid for a total daily dose of 3,900 mg) administered for up to 12 weeks was effective in treating moderate to moderately severe chronic OA pain of the hip or knee and was generally well tolerated (126).

Acetaminophen continues to be well tolerated by patients, but they should be made aware of acetaminophen dosing limitations due to potential hepatotoxicity, particularly if taken at excess doses for prolonged time periods as could occur in patients with a chronic, progressive disorder. Specifically, for patients with normal hepatic function, the safe dosing limit on average is felt to be 4 g/24 hours. This limit is lower in those with preexisting hepatic disease such that the maximum dose is tentatively set at one half of the maximum dose (i.e., 2 g) for those patients with normal hepatic function, and regular LFT monitoring is advisable. Since chronic alcohol abusers (defined as >3 drinks/day) are at increased risk of liver toxicity from excessive acetaminophen use, these patients should be considered for the above dose adjustment (1). This recommendation may be overly cautious as reports of severe hepatotoxicity almost invariably involve acetaminophen doses that exceed the recommended ones and have often involved substantial overdose.

Another important advantage of acetaminophen is that it rarely causes medication interactions. One important exception is acetaminophen and the concomitant use of warfarin as acetaminophen can prolong the half-life of warfarin (127). Although this might only be clinically significant in patients at higher levels of anticoagulation who are chronically taking acetaminophen, the INR should be closely monitored (128). As the algorithm implies and epidemiologic studies have shown, eventually the knee or hip OA patient will require alternative or additional analgesia as the disease progresses and pain increases (129).

In summary, acetaminophen remains an inexpensive and well-tolerated medication (few side effects, toxicities, or drug-drug interactions) that provides modest pain relief for those with OA, and as a result, it should be considered a first-line

**TABLE 31.3 Risk Factors for Renal Toxicity in Patients Requiring Chronic NSAID or COX-2 Inhibitors**

- Serum creatinine  $\geq 2.0$  and any one or more of the following:
  - Age  $> 65$
  - Comorbid medical condition that adversely affects renal blood flow
  - Concomitant use of medications that alter renal prostaglandin synthesis
  - Hypertension
  - Congestive heart failure
  - Diuretics
  - ACE inhibitors

analgesic in OA and if necessary can be used as an adjuvant medication in more advanced diseases (130).

For patients with hip or knee OA but without risk factors for renal dysfunction, an oral anti-inflammatory agent can be considered. Trials and reviews have shown that NSAIDs have better efficacy than acetaminophen or placebo for OA pain (121,131–133), especially in patients in whom acetaminophen has been previously trialed without significant relief.

An important question is whether the patient is taking Coumadin. If yes, then celecoxib (Celebrex), the only COX-2 inhibitor that is currently available at the time of this writing, should be used instead of a traditional NSAID. Celecoxib does not inhibit thromboxane synthesis and therefore lacks an antiplatelet effect (134). However, since celecoxib prolongs the half-life of Coumadin on average by 11%, the INR must be followed appropriately, particularly during the first 2 weeks when celecoxib is begun or when the dose is changed.

A patient's risk of gastrointestinal (GI) bleeding (Table 31-4) must be considered when deciding between an NSAID with or without gastroprotection and a celecoxib. Celecoxib is not as likely to cause GI toxicity because selective COX-2 inhibitors suppress COX-2 enzymes responsible for pain without affecting the COX-1 enzymes that regulate endogenous prostaglandin production that provides GI protection.

If GI bleeding risk factors are present, the psychiatrist has three options to consider (see Fig. 31-2). One option is celecoxib since trials have found it to be as effective as nonselective NSAIDs (e.g., naproxen and diclofenac) but cause significantly fewer serious upper GI events (135). Another factor is whether the patient has a history of a sulfonamide allergy since this would eliminate celecoxib as an option. A second option is to combine an NSAID with a form of gastro-protection, specifically, a proton pump inhibitor (PPI), an H<sub>2</sub>-blocker, or misoprostyl (Cytotec). PPIs can be used with a traditional NSAID. PPIs appear to have better efficacy in preventing NSAID-induced GI lesions, as compared with misoprostyl and H<sub>2</sub>-blockers (136–138). Although, one study revealed that PPIs were not superior to high-dose misoprostyl (800 µ/day) for the prevention of NSAID-induced gastric ulcers (139). However, there are potential adverse effects associated with high-dose misoprostyl that limits its widespread use. As misoprostyl is a prostaglandin analogue, it causes smooth muscle contraction,

thus explaining its contraindication in females of childbearing age as inadvertent use during pregnancy could lead to spontaneous abortion from uterine smooth muscle contraction with subsequent fetal expulsion. GI tract smooth muscle contraction also can lead to unpleasant side effects such as diarrhea, flatulence, and cramping. Arthrotec is a combination of an NSAID (diclofenac) and Cytotec (misoprostyl) along with an enteric coating and should be considered if the decision has been made to pair a traditional NSAID with misoprostyl. With respect to PPIs, comparisons between these found that they provide equivalent, effective, and well-tolerated prophylaxis against NSAID-induced GI lesions (140).

The third option is to choose a nonacetylated salicylate, which will be discussed later in the chapter. A final consideration in patients who need anti-inflammatory analgesics but are at very high risk for recurrent GI ulcer bleeding is combination therapy with a celecoxib and a PPI (141). The addition of a PPI to celecoxib should also be considered in patients older than 75 years, since additional GI protection is gained (142).

CV toxicity from traditional NSAIDs is another factor to consider when choosing this class of medications. One theory is that patients using propionic acid derivative NSAIDs (e.g., ibuprofen, naproxen) have the potential to interfere with the aspirin's antiplatelet activity (143). Therefore, patients already on aspirin for known coronary artery disease may be at increased risk of myocardial infarction if taking a propionic acid derivative NSAID. Meta-analyses reveal that the risk of serious CV events exist for both selective and nonselective NSAIDs and that among the nonselective NSAIDs, diclofenac had the highest risk for an adverse CV event (144).

COX-2 inhibitors have received significant public attention due to their associated CV toxicity. Rofecoxib (Vioxx) was voluntarily removed from the market in 2004 after a clinical trial that was investigating the cancer prevention properties of Vioxx found an increased risk of myocardial infarction and stroke (145). Valdecoxib (Bextra) was then similarly removed due to increased CV risks. One possible explanation of increased CV toxicity is that selective COX-2 inhibition reduces levels of COX-2–derived prostacyclin that increases the risk of thrombosis (146). Celecoxib remains on the market, but it has two important black box warnings for CV and GI risks. Celecoxib has a lower CV risk profile but possibly an increased GI risk profile compared to previously available COX-2 inhibitors. Although this suggests lack of complete selectivity for COX-2 suppression with celecoxib, a meta-analysis revealed that celecoxib had a lower rate of GI bleeding and ulcers as compared to nonselective NSAIDs (147). In addition, celecoxib at supratherapeutic doses appears to have a safer cardiorenal profile as compared with traditional NSAIDs (e.g., ibuprofen or diclofenac) at standard doses (148). Research does suggest that COX-2 inhibitors may confer a decreased risk of CV events as compared with nonselective NSAIDs in aspirin users at high CV risk (149). Although COX-2 inhibitors appear to have a lower risk of CV events when compared to traditional NSAIDs, the recommendation is to use the lowest effective dose for the shortest duration (150), especially

**TABLE 31.4** GI Bleeding Risk Factors in Patients Chronically Taking NSAIDs

- Age > 65
- History of PUD or UGI bleeding
- Concomitant corticosteroids or anticoagulants
- Smoking
- Alcohol use
- Poor general health
- Longer duration of NSAID treatment

in those patients with significant risk factors for CV events. Although current research provides some guidelines concerning the use of selective and nonselective NSAIDs and their inherent CV risks, future research will hopefully provide definitive answers regarding these issues.

Besides oral anti-inflammatories, two other options for delivery of anti-inflammatory medications include a topical NSAID and a topical NSAID patch. A topical prescription NSAID patch, Flector (diclofenac 1.3% epolamine topical patch) patch, was FDA approved in 2008. Flector is indicated for the topical treatment of acute pain due to minor strains, sprains, and contusions. A randomized controlled trial also found that it was effective in the short-term treatment of pain due to symptomatic knee OA (151). Another diclofenac patch (diclofenac hydroxyethylpyrrolidine) was previously trialed and was found to be an effective and safe treatment for patients with symptomatic knee OA (151). Off-label use for patients with painful OA, particularly affecting the hands and knees, is likely to begin. Precautions and contraindications for Flector are similar to those for oral NSAIDs, and future research may reveal specific clinical situations where an NSAID patch is preferred to oral NSAIDs.

The algorithm in Figure 31-2 shows that for those patients whose pain and/or inflammation cannot be managed with oral anti-inflammatories, for those experiencing side effects that preclude further use of oral anti-inflammatories, or for those patients with renal risk factors that preclude the use of oral anti-inflammatories, the clinician can choose among several options. For patients with pain due to knee OA, these choices include viscosupplementation if it has not been previously tried or has been previously successful, or a corticosteroid injection with or without subsequent viscosupplementation, especially if there are signs of inflammation. Another option is tramadol (Ultram) or one of its variants such as its combination form with acetaminophen (Ultracet) or its once per day extended-release form (Ultram ER). Tramadol may be used in addition to NSAIDs or as an alternative to single therapy with high-dose NSAIDs (152).

The available literature to support use of tramadol compounds in the treatment of OA pain has grown since the last edition of this book. Studies have concluded that tramadol is a safe and effective option for the treatment of OA pain, more effective than placebo and comparable in efficacy to traditional NSAIDs (e.g., ibuprofen) (153,154). A Cochrane database systematic review concluded that tramadol or tramadol/acetaminophen decreases pain intensity, provides symptomatic relief, and improves function in patients with OA, but these benefits are somewhat small (155). It has been shown, however, to effectively treat breakthrough pain in OA that is moderately severe in intensity (156).

Tramadol's relatively short duration of action (qid dosing) can be a disadvantage for a chronic painful condition, but tramadol extended release allows for qd dosing. Another advantage is that since the osteoarthritic patient population tends to be older, tramadol's lack of GI bleeding potential and lack of renal toxicity are major advantages. In addition,

it does not cause exacerbations of hypertension or congestive heart failure (157). GI side effects (e.g., constipation, nausea, and vomiting) and central nervous system (CNS) side effects (e.g., dizziness, somnolence, and headaches), however, were the most commonly reported adverse events (158,159). Dizziness remains a significant concern, especially for older patients, and can be detrimental to rehabilitative efforts. Dose titration does appear to lower the incidence and severity of these GI and CNS side effects and should be considered when prescribing tramadol, tramadol/acetaminophen, or tramadol extended release (160–162). Tramadol is associated with extremely low rates of abuse and dependence, no significant tolerance, and mild withdrawal symptoms when compared to other opioid compounds (163,164). Overall, the literature supports the use of tramadol for OA pain as it is a well-tolerated medication in comparison with other opioid compounds.

Ultracet (tramadol 37.5 mg and acetaminophen 325 mg) is another current option to consider. Because it was FDA approved in 2001 for the treatment of acute pain, it is not included in the 2000 ACR OA guidelines. It offers convenience for those patients who are taking both acetaminophen and tramadol. It provides similar levels of pain relief but with an improved side-effect profile as compared with stronger opioids (165–167). The literature also supports its use along with selective and nonselective NSAIDs. Adding tramadol/acetaminophen for patients with persistent OA pain despite ongoing therapy with nonselective NSAIDs or COX-2 inhibitors resulted in improved pain relief and improved physical function (168,169). Tramadol/acetaminophen was also shown to be an effective add-on therapy to help manage painful OA flares in the elderly and was generally well tolerated in this group of patients (170). As was noted above, a Cochrane systematic review concluded that tramadol/acetaminophen decreases pain intensity, provides symptomatic relief, and improves function in patients with OA, but these benefits are somewhat small (155).

Ultram ER or extended-release tramadol became available in 2005 and, therefore, was not included in the 2000 ACR guidelines on OA (1). Ultram ER is approved for the treatment of moderate to moderately severe chronic pain and is recommended in adults who require around-the-clock treatment for their pain for an extended time period (171). It is an option that offers a degree of convenience for those patients taking tramadol tid or qid. Ultram ER appears to be well tolerated for an opioid compound and has similar common adverse effects (dizziness, nausea, constipation, headache, and somnolence) as Ultram (171). It has proven to be safe for long-term use in patients with OA (172). It is well tolerated and more effective than placebo and is as effective as tramadol for treating pain associated with knee or hip OA (173–175). Overall, extended-release tramadol has been shown to effectively reduce pain and improve physical function in those with OA, and its convenient dosing schedule may allow it to play an increasing role in the treatment of OA (176,177).

If a patient continues to have pain despite one of the tramadol compounds and/or is intolerant to these, then opioid

analgesics should be considered (see Fig. 31-2). Like tramadol, the lack of GI bleeding potential and lack of renal toxicity associated with pure opioid analgesics are a major advantage in elderly patients with OA. Certain groups of OA patients appear to be best suited for opioid analgesics, including those who are not good candidates for joint replacement surgery. For example, while some patients are too young for this surgery and would be best suited for surgery at an older age so that they would not be as likely to require revision surgery, others are “too old” and otherwise too limited in their daily activities to justify this form of surgery. Other patients are too medically ill for arthroplasty, and finally, some patients are too afraid to undergo surgery. Each of these patient groups should at least be considered for chronic opioid analgesics. Along these lines, the 2000 ACR guidelines have revised their wording from the previously published 1995 guidelines regarding this issue. The 1995 guidelines stated that: “Opioid analgesics, such as propoxyphene, codeine, or oxycodone should be avoided for long-term use, but short-term use may be helpful for the treatment of acute exacerbations of pain” (178). By contrast, the 2000 guidelines state: “Patients who do not respond to or cannot take tramadol and who continue to have severe pain may be considered candidates for more potent opioid therapy.” This change in wording is reflective of the general sentiment in musculoskeletal medicine that opioid analgesics may be appropriate in some chronic nonmalignant pain conditions. Although the consensus is that these medications can be used for chronic management of OA pain, a recent meta-analysis of randomized controlled trials concluded that the long-term efficacy and safety of these drugs for OA are yet to be determined due to the short mean trial duration (178).

Numerous studies have supported the safety and efficacy of opioid analgesics in patients with moderate to severe OA pain (179–182). They can be effectively used to treat OA pain that has not responded to combined acetaminophen, NSAID, or tramadol therapy. These patients may be started on low-dose opioids, and the dose may be titrated as needed and as tolerated (183). Unlike other medications that have a “therapeutic ceiling,” they can be titrated upward to achieve a satisfactory analgesic effect, as long as the patient can tolerate the dose (130). Another consideration is to add an opioid to ongoing NSAID therapy since this combination provides improved pain control and sleep quality (184,185). NSAIDs and opioids are also mutually dose sparing, and combining relatively low doses of a drug from each class provides synergistic analgesia while limiting toxicity, which may improve patient tolerance and compliance with these medications (186).

There are a wide variety of choices in regard to opioid analgesics, including opioids of various durations and opioids of various routes of administration. One option that is gaining popularity in the management of chronic pain is topical patches, such as fentanyl transdermal (Duragesic). Clinical trials have demonstrated that transdermal fentanyl can significantly improve pain control, function, and quality of life for patients with OA of the knee or hip (187,188). Additional research has shown that therapy with transdermal fentanyl may be

initiated in patients who were pretreated with nonopioid analgesics or weak opioids and can be tapered off without major complications (189).

Intra-articular opioids are another option to consider in the setting of an acute exacerbation of pain in patients with chronic OA. Previous studies have demonstrated significant pain reduction with intra-articular morphine as compared with intra-articular saline in the setting of chronic pain due to OA (190,191). Although effective, this option has only been shown to provide a short duration of benefit (5 to 7 days). Therefore, unless a longer duration of benefit can be shown, intra-articular morphine should be considered in the setting of an acute exacerbation of OA pain in patients in whom previous corticosteroid injections were ineffective or contraindicated (130).

A final option to consider for knee OA and an option for hand OA includes topical analgesics (see Fig. 31-2). The topical application of analgesic medications is a viable supplementary treatment that is available to patients with OA of joints that are superficial enough to allow medication penetration. By contrast, these medications are relatively inaccessible to deeper lying joints such as the hip and spine. Topical medications can be used as adjunctive therapy or sometimes as an alternative to oral medications. Topical medication administration has the advantage of local medication delivery to the joint at high concentrations with minimal systemic side effects. By contrast, only a small percentage of medication administered systemically reaches the joint. Capsaicin, topical salicylate, and topical NSAIDs are the three medication categories cited in the ACR guidelines. Since the time that those guidelines were published, topical lidocaine (Lidoderm patch) has become an off-label option.

Capsaicin, derived from jalapeno (aka “hot chili”) peppers, provides analgesia by reversible depletion of substance P and neuropeptide from unmyelinated C-fiber afferent nerve endings. There are various capsaicin-containing preparations, some of which contain other topically active substances. Because it often takes at least 2 weeks of substance P depletion before analgesia occurs and there is initial stinging from a flare response that occurs when neuropeptides are depleted from nerve endings, initial compliance during the first 2 weeks of treatment can be poor. There is some evidence that substance P enhances cartilage degradation (192), and therefore, an antisubstance P agent such as capsaicin has been implicated as a potential disease-modifying agent in OA (193). Randomized controlled trials and a meta-analysis have found capsaicin superior to placebo for the treatment of OA pain, especially in patients with painful hand OA (194,195). Localized burning is the most commonly reported adverse effect and has been reported in approximately 50% of users (194,196). Because many patients cannot tolerate this adverse effect and as a result discontinue its use, capsaicin has been studied in combination with glyceryl trinitrate. Capsaicin combined with topical glyceryl trinitrate resulted in a decrease in analgesic consumption, likely due to the synergistic analgesic effect and improved tolerability of these two agents in combination as compared to either agent alone (197). Unfortunately, glyceryl trinitrate has been

shown to accelerate cartilage degeneration and subchondral bone sclerosis in the setting of ovine OA (198). Until additional evidence is available, it is unclear if capsaicin should be combined with glyceryl trinitrate. Another factor in patient compliance is the recommendation to apply topical capsaicin four times a day, which makes long-term compliance very difficult. Tapering the dose to twice a day has been suggested as a way of improving long-term compliance and reducing cost without losing efficacy (199). In summary, topical capsaicin remains an option as an adjunctive therapy in patients with OA of superficial joints (e.g., joints of the hand) if they are tolerant of its common adverse effect; although evidence-based support for its use in OA is limited, its potential role as a disease modifying agent is intriguing.

Over-the-counter topical salicylates have been used for years by patients with OA and other types of musculoskeletal pain. These preparations have been extensively marketed and include methyl salicylate (e.g., Bengay, Icy Hot, and Flexall) and trolamine salicylate (e.g., Sportscreme, Aspercream). Topical salicylates may be found alone or combined with other topical medications (e.g., capsaicin, camphor, and menthol) into topical creams, liniments, lotions, and rubs. In general, peer reviewed literature on the safety and efficacy in OA is limited. A systematic review of available clinical trials concluded that topical salicylates may be efficacious acute pain treatment, but they have only moderate to poor efficacy for musculoskeletal and arthritic pain (200). In addition, trolamine salicylate failed to demonstrate efficacy as compared with placebo in a randomized double blind crossover study in patients with knee OA (201). Overall, topical salicylates are well tolerated and adverse events have been rare in studies of acute pain; no adverse events occurred in the previously listed trials on knee OA, but topical methyl salicylate preparations may cause irritant or allergic contact dermatitis and anaphylactic reactions. Therefore, physicians should be aware of potential dangers from topical preparations containing methyl salicylate (202). In summary, topical salicylates when used properly are safe and may be beneficial in OA, although evidence-based support is very limited. The available literature also suggests that methyl salicylates are probably more effective than trolamine salicylates, especially when combined with penetration-enhancing substances (e.g., menthol and camphor).

The ACR's inclusion of topical NSAIDs among its list of recognized medication categories is based in part on its efficacy in multiple placebo-controlled trials of topical NSAIDs in the treatment of osteoarthritic pain (203,204). Several short-term studies (approximately 2 weeks in duration) have concluded that topical NSAIDs help relieve knee OA pain compared with placebo (205–208). In addition, a meta-analysis concluded that topical NSAIDs are effective for a longer duration (>4 weeks) of pain relief in knee OA (209). Although there are significantly fewer controlled trials comparing topical NSAIDs with oral NSAIDs, these have generally shown equal efficacy and less GI side effects (210). In contrast to their relatively recent recognition in the United States, topical NSAIDs have been available in Europe for

many years (211,212). In the United States, they have been used infrequently, and this may be because previously they were available only through compounding pharmacies and were rarely covered through traditional prescription medication plans. Voltaren gel (Diclofenac topical) received FDA approval in 2007 for the treatment of OA pain. Voltaren Gel is recommended for the treatment of OA pain in joints amenable to treatment with topical preparations, such as the knees and hands. Similar to capsaicin, it is to be applied four times a day. A dosing card onto which the patient squeezes the dose can help the patient to comply with the recommended dose of 4 g/day per lower limb joint and 2 g/day per upper limb joint. The most common adverse reactions were application site reactions (e.g., dermatitis), but the same warnings and precautions that exist for oral NSAIDs (e.g., CV, GI, and renal risks) exist for this topical preparation (213). Voltaren Gel has limited peer reviewed literature available to support its use, but previous studies on other diclofenac preparations have demonstrated safety and efficacy for the treatment of knee OA (214–216).

Another diclofenac product, diclofenac 1.3% (Flector patch), is indicated for minor sprains, strains, and contusions. Although it is not officially indicated for knee OA pain, a randomized controlled trial found it to be effective in short-term treatment of symptomatic knee OA (217).

Topical NSAID use in the United States will likely increase and gain increased acceptance amongst physicians and patients in part due to our aging population who will need treatment options for OA that offer a lower risk of adverse events. In a recent randomized controlled trial, the authors concluded that topical NSAIDs may be a useful alternative to oral NSAIDs for treatment of knee OA in the elderly since efficacy is equivalent and there are fewer minor side effects (218). As a result, physicians who treat OA should be very aware of topical NSAIDs as a possible treatment option.

The final topical option to consider is a 5% topical lidocaine patch (Lidoderm patch). It was FDA approved in 1999 for the treatment of pain associated with postherpetic neuralgia but now is being used in an off-label fashion for a variety of painful musculoskeletal conditions, including OA. The lidocaine patch 5% releases lidocaine that penetrates into the skin and provides an analgesic effect without local anesthesia; and unlike transdermal medications, it does not result in clinically significant serum levels even in the setting of chronic use (219,220). Although its package label indicates that a maximum of three patches may be applied at a time and that it can be applied for 12 hours/day, patients report using it for up to 24 hours without adverse effects on their skin (221). In one published study on knee OA, the lidocaine patch 5% was effective as an add-on therapy for reducing pain and stiffness and improving physical function in a group of patients with knee OA pain that had not responded completely to prior analgesic therapy (222). Another study found that 2 weeks of treatment with the lidocaine patch 5% significantly improved the quality of pain, as assessed by a neuropathic pain scale, in patients with moderate to severe

knee OA pain (223). In regard to patient tolerance, it is well tolerated with the main side effect reported in these clinical OA trials being an application-site local skin irritation, which was generally mild and usually did not require medication discontinuation. In regard to safety, no serious adverse events were observed during more than 120,000 patch hours involving patients who have used the patch in clinical trials for up to 8.7 years (219,224). In addition, no drug-drug interactions have been noted in clinical trials (220), but the manufacturer still recommends that the lidocaine patch be used cautiously in patients already on a class I antiarrhythmic (221). Controlled clinical trials are still needed to determine whether this agent is indeed effective in patients with OA of the knee and/or other joints, but it does appear to be reasonable to trial a topical lidocaine patch as an adjunctive agent in patients with OA who have failed to respond adequately to the previously listed agents.

The final topic of discussion for oral medications is that of pharmacologic agents that could play a role in the future management of OA. New NSAIDs, both oral and topical, and additional COX-2 inhibitors, if they in fact receive FDA approval, could provide additional treatment options. A new anti-inflammatory class, known as lipoxygenase (LOX)/cyclooxygenase (COX) inhibitors (e.g., licofelone), inhibits leukotriene synthesis so as to theoretically increase the anti-inflammatory effect while reducing the risk of prostaglandin inhibition–related GI toxicity (225). If LOX/COX inhibitors become available in the United States, they may prove to be as effective yet safer than COX-2 inhibitors and/or traditional NSAIDs. Intra-articular (IA) injections that are currently available (e.g., corticosteroids, hyaluronic acids) may be redesigned into suspensions or hydrogels to achieve sustained release of the active ingredient to provide long-term pain relief and potential functional improvement (226). The most intriguing agents being investigated are disease modifying OA drugs (DMOADs), which target various steps in the cascade of events leading to arthritic changes in the joint. Clinical trials are currently underway for DMOADs, such as interleukin-1b inhibitors, and they may prove to be the most promising new agents available (227), since their goal is to halt the progression of OA.

### Injectable Treatment Options

Corticosteroid injections should be considered for patients with hip and/or knee OA who continue to have pain despite acetaminophen, particularly if they are at particular risk for renal dysfunction (see Table 31-4; Fig. 31-2).

If the patient is deemed to have any of these risk factors for renal dysfunction, then consideration should be given for corticosteroid injections, especially for patients with hip or knee OA, and for viscosupplementation (the intra-articular administration of a hyaluronate-containing solution [aka hyaluronate, sodium hyaluronate, HA] into osteoarthritic joint synovial fluid). For knee OA patients, corticosteroid injections can be potentially used in conjunction with a course of viscosupplementation (see Fig. 31-2). The need for fluoroscopic or ultrasound guidance for hip corticosteroid injection very frequently

precluded these injections in the past. However, with image guidance becoming increasingly available to musculoskeletal physiatrists, hip joint corticosteroid injections will probably be utilized more frequently.

A Cochrane review of 26 trials of IA corticosteroids for knee OA involving 1,721 patients found short-term efficacy with few side effects (228). IA corticosteroids were compared with placebo and viscosupplementation. IA corticosteroids were found to be more effective for pain reduction than IA placebo up to 3 weeks postinjection, but not from 4 to 24 weeks. No statistically significant differences were found between IA corticosteroids and viscosupplementation at 1 to 4 weeks postinjection. From 5 to 13 weeks, viscosupplementation showed superior efficacy for several efficacy parameters. These findings suggest a similar onset of action for IA corticosteroids and viscosupplementation but that viscosupplementation provides greater long-lasting benefit. Another meta-analysis on the efficacy of IA corticosteroids for knee OA showed benefit that lasted for only 2 weeks (229). Additional data from this meta-analysis suggested that high corticosteroid doses (i.e., doses of 50 mg equivalent of prednisone) may be required to achieve a longer response.

The analgesic mechanism of action of corticosteroid injections is not completely understood despite detailed study of this phenomenon (230–239). Furthermore, aspiration of an associated joint effusion as is generally performed at the time of the corticosteroid injection also probably contributes to the analgesic effect through removal of inflammatory mediators and a decrease in mechanical pressure from capsular distension.

Although recommended intra-articular corticosteroid dosages have not been determined with certainty for any joints as intrasynovial steroid dose-response curves have not been developed, a generally accepted dosage range for the knee is 40 to 80 mg of methylprednisolone acetate (Depo-Medrol) or its equivalent. “Steroid arthropathy” (accelerated OA of a synovial joint) can potentially occur as a result of repeat injections but remains a very controversial topic with respect to incidence, mechanism of action, and the number of injections that should not be exceeded (240). There is laboratory evidence from studies in nonprimate OA animal models of a deleterious effect on proteoglycan synthesis that is believed to make cartilage more susceptible to injury (241–243). Another proposed mechanism is analgesia leading to a Charcot-like joint (243). The most common dosing limit quoted in the literature is 3 per year and 20 in a lifetime into any given joint (244).

In patients with knee OA who also have signs of inflammation, the sequential performance of a corticosteroid injection followed by a course of viscosupplementation is an option (245,246). The rationale is that the reduction of inflammatory mediators by the corticosteroid injection limits the degradative effect that these mediators subsequently have on the viscosupplement.

Alternatively one can simply consider a course of viscosupplementation as there appears to be an anti-inflammatory effect from viscosupplementation. Basic science research has led to the discovery of several cell surface proteins with specific HA-binding sites that mediate biologic responses, and the

author as well as others have noted the “drying up” of initially inflamed knee joints during a viscosupplementation cycle (247–249).

Viscosupplementation is FDA approved for patients with knee OA who continue to have pain despite regular doses of a simple analgesic such as acetaminophen and nonpharmacologic therapy (see Fig. 31-2). Although there is evidence supporting several different potential mechanisms of action, which have been described in detail elsewhere, its exact overall mechanism is not known with certainty (Table 31-5) (250–311).

It remains controversial if viscosupplements exert a chondroprotective effect, even though there is evidence from *in vitro* studies, animal studies, and limited evidence in humans (312,313). Less controversial are the conclusions from several different investigators that viscosupplementation improves pain and function (314–317). There is also some evidence that the efficacy of a viscosupplement may be enhanced by concomitant therapeutic exercise, particularly quadriceps strengthening (318,319). Pain relief from viscosupplements has been shown to be of longer duration compared with other pain-relieving interventions such as arthrocentesis and corticosteroid injections (316,320). The only contraindication to viscosupplementation with a nonbacterially fermented viscosupplement (all current viscosupplements other than Euflexxa) aside from the contraindications to joint injection procedures in general includes the rare circumstance of true allergy to a viscosupplement. This situation is predicted by an allergy to avian proteins such as eggs or feathers.

At the time of this writing, there are five viscosupplements available for use in the United States. These include hylan GF-20 (Synvisc); three formulations of sodium hyaluronate that differ somewhat in molecular weight including Hyalgan, Supartz, and Orthovisc; and a bacterially fermented sodium hyaluronate preparation known as Euflexxa. Synvisc is chemically unique compared to the other viscosupplements in that its molecular weight is higher as it is chemically cross-linked with

formaldehyde and divinyl sulfone. The question as to whether there is a correlation between clinical efficacy and higher molecular weight is controversial and remains unsettled by both individual studies and by meta-analysis, which noted significant interstudy heterogeneity in estimating efficacy (321–326). Cross-linking may be a disadvantage given the severe acute inflammatory reactions (SAIRs) seen with Synvisc that have not been reported with the noncross-linked viscosupplements. The exact mechanism of this side effect is unclear but possibly relates to the divinyl sulfone and/or formaldehyde cross-links.

Although efficacy of viscosupplementation is in part related to the radiographic stage of OA, with less efficacy seen for higher grades of OA (91% of grade I OA patients compared to 58% of grade IV OA patients reported that they felt much better or better), this is likely to be true of any nonsurgical intervention (327). Furthermore, there is evidence that viscosupplementation can delay the need for TKR in advanced OA patients (328–330).

### Other Image-Guided Injections for OA

Physiatrists are increasingly performing image-guided injection procedures, including fluoroscopy-guided and ultrasound-guided procedures, both into the spine and into the axial skeleton. The spinal injections that are performed in OA patients with osteoarthritic-related spinal pain include epidural injections and facet-related procedures. For example, patients with cervical and lumbosacral spinal stenosis often receive these injections as a symptomatic treatment for associated radicular and axial pain. Facet joint injections, medial branch blocks, and radiofrequency ablation are performed on patients with facet joint OA.

While most of the spinal injection procedures in OA patients utilize fluoroscopic guidance, ultrasound is becoming increasingly available. Thus, injection procedures on peripheral osteoarthritic joints such as the hip and knee are now being performed utilizing either ultrasound or fluoroscopic guidance. Image guidance is also particularly helpful into other peripheral joints that may be otherwise difficult to inject due to severe osteoarthritic narrowing.

There are several reasons why it is likely that image-guided injection procedures will become increasingly performed by physiatrists who treat OA patients. First, as the population continues to age, the incidence of OA is also increasing. Second, physiatrists are becoming more adept at image-guided injections as part of their treatment armamentarium. Finally, studies on viscosupplementation into other osteoarthritic joints continue to be conducted. If the FDA eventually approves viscosupplementation for other joints besides the knee, this will most likely lead to an increased performance of image-guided hip joint injections.

# Disorders of the Cervical Spine

The intricately designed and highly mobile cervical spine is routinely subject to unique mechanical stresses that predispose the spinal elements to degenerative change. Three common symptom complexes are associated with the degenerative cascade of the cervical spine. These include cervical axial pain, radiculopathy, and myelopathy (1,2). These syndromes may occur in isolation or in combination. Axial pain, arising from degenerative discogenic or zygapophyseal joint pain generators, is more commonly described in the middle decades of life (3). Spinal nerve root pathology and radicular syndromes may arise from an acutely offending disc injury or more gradually evolving and degenerative neural foraminal compromise (4,5). Myelopathic symptoms occur when the spinal cord is affected by central canal stenosis (6–8). This chapter will review these common degenerative cervical syndromes, the cervical spine in rheumatoid arthritis (RA), and rehabilitative approaches.

## ANATOMY AND BIOMECHANICS

The cervical spine is composed of seven vertebrae and five intervertebral discs. The C1 and C2 segments are anatomically unique. The C2 through C7 bodies articulate anteriorly through the intervertebral discs and uncovertebral joints, or joints of Luschka, and posteriorly through the zygapophyseal joints (Fig. 32-1). The occipito-atlanto-axial or Oc-C1-C2 complex is a specialized upper cervical segment that allows for a significant range of motion between the head and upper torso (9). The articulations of this segment are composed of synovial joints with no intervertebral discs. The basic structure of this segment is a biconcave ring of C1 interposed between the convex condyles of the occiput (Oc) above and the C2 lateral masses below. The odontoid, or dens, projects upward from the C2 vertebrae, providing a post to which the C1 ring and Oc are directly anchored (9). The Oc is attached to the odontoid predominantly by the alar ligaments and also by the less significant apical and upper arms of the cruciform ligament (10). The C1 ring is bound to the odontoid by the sturdy transverse arm of the cruciform ligament as well as the accessory C1-2 ligaments and the C1-2 joint capsules (11) (Fig. 32-2).

In the lower cervical spine, the intervertebral discs contribute to approximately one fourth of the height of the cervical

column (12,13). The dimensions of the cervical disc, which is thicker anteriorly than posteriorly, contribute to the cervical spine's lordotic curvature (14). The cervical disc allows for a greater degree of motion than do the discs in the lumbar region, as the disc-to-vertebral body height ratio in the cervical region is 2:5, compared with a 1:3 ratio in the lumbar spine. The anterior longitudinal ligament runs along the anterior vertebral body and discs, providing structural support in limiting cervical extension. The posterior longitudinal ligament supports the disc and body posteriorly, stretching in flexion and relaxing with extension. The superficial ligamentum nuchae is a dense midline band that extends from the Oc to the spinous process of C7. Proceeding ventrally in the midsagittal plane, the supraspinous ligament, interspinous ligament, and ligamentum flavum are encountered in order, each contributing to stability in flexion (9).

The external component of the intervertebral disc is comprised of the annulus fibrosus, which consists of multiple lamellae of type I and II collagen. The annulus encapsulates the internal nucleus pulposus. The fiber direction of the annular lamellae alternates, with each consecutive layer oriented opposite to the adjacent fibers (14). This structural arrangement uniquely allows the annulus to accommodate angular motion while providing stability against torsion and shear. The intervertebral discs are separated from the vertebral bodies by the end plates (13,15). The end plates are composed of hyaline and fibrocartilage and form a permeable surface through which nutrients may pass between the cancellous bone of the vertebral body and the intervertebral discs. The end plates are vascularized during fetal life, but their vessels involute during the first 10 to 15 years of development (16). Thereafter, the essentially avascular intervertebral disc receives its nourishment through the end plates and vessels circumscribing the outer annular fibers (12,14). The nucleus pulposus is a semifluid gel, composed predominantly of water, which represents 40% to 60% of the intervertebral disc and allows for deformation and accommodation of movement and compressive loading. With aging, the nucleus is slowly replaced by fibrocartilage, and by the end of the first decade of life, the distinction between the nucleus and surrounding annulus begins to lessen (12). The innervation of the outer one third to half of the annulus fibrosus has been demonstrated (17,18). The anterior disc is innervated by branches of the vertebral nerves and sympathetic

**FIGURE 32-1.** Articulated cervical vertebrae: lateral view. (From Anderson JE. *Grant's Atlas of Anatomy*. 8th ed. Baltimore, MD: Williams & Wilkins; 1983, with permission.)

trunks. The posterior disc, posterior longitudinal ligament, anterior dura, and dural root sleeves are innervated by a posterior plexus derived from the sinuvertebral nerves (19) (Fig. 32-3).

The uncovertebral joints or joints of Luschka are anterior articulations found between the third through seventh vertebrae that share in load bearing and are often affected by degenerative change (12). The zygapophyseal joints are planar synovial joints, which are created by the inferior and superior articular processes of adjacent vertebrae. Each joint is composed of circular or ovoid facets that are covered by articular cartilage and enclosed by a fibrous joint capsule (20). The zygapophyseal joint may include fibroadipose menisci located at the ventral and dorsal joint poles. These menisci are thought to be drawn from the joint cavity during joint gliding to cover those articular surfaces that become exposed during such motions (21) (Fig. 32-4). The cervical zygapophyseal joints are innervated by articular branches originating from the medial branches of the cervical dorsal rami. Each cervical zygapophyseal joint receives a dual innervation from the medial branches arising from the dorsal rami above and below. The medial branches of the C3 dorsal ramus are unique. A deep C3 medial branch contributes to the C3-4 joint innervations, whereas the larger superficial medial branch of C3, also known as the third occipital nerve,

**FIGURE 32-2.** Median section of Oc C1-2 complex. (From Anderson JE. *Grant's Atlas of Anatomy*. 8th ed. Baltimore, MD: Williams & Wilkins; 1983, with permission.)

innervates the C2-3 joint (20). Beyond the C2-3 joint, the third occipital nerve innervates the semispinalis capitis and supplies cutaneous sensation to the suboccipital region. This is the only dorsal ramus below C2 that has a cutaneous distribution (22).

From C2-3 through C5-6, the zygapophyseal joints are angled at approximately 45 degrees, with the longitudinal axis of the cervical spine, with a typically steeper angle at C6-7 (23). The superior articular processes are progressively taller at the more caudal segments, with the upper ends of the joints extending further above the level of the segmental intervertebral disc. The orientation of the zygapophyseal joints allows them to resist both forward and downward displacement of the vertebral body. As the zygapophyseal joint of the upper cervical segments are relatively more horizontally oriented, they contribute more to bearing axial loads than do the more caudal segments. The orientation of the zygapophyseal joints dictates the nature and magnitudes of movement in the cervical spine (20).

The primary motion of the Oc-C1-C2 complex is flexion and extension at both Oc-C1 and C1-2, axial rotation only at C1-2, and minimal lateral bending at Oc-C1 (9). The Oc-C1 articulation allows for approximately 10 degrees of flexion and 25 degrees of extension. Rotation of 45 degrees in either rotation can be observed at the C1-2 joint (24,25). A useful approximation of the range of motion allowed by each segment between C2-3 and C7-T1 is 10 degrees of total range from flexion to extension, as well as 10 degrees of lateral bending and axial

New York: Churchill Livingstone; 1994:65–76, with permission.)

rotation to each side. Flexion and extension and axial rotation tend to be the greatest in the midcervical region, decreasing both above and below. Lateral bending is typically greatest at C2-3 and diminishes caudally (26). Instability of the cervical

region has been defined as a horizontal displacement of the vertebral body during flexion and extension of greater than 3.5 mm or angular change of greater than 11 degrees (27).

The neural elements of the cervical spine include the spinal cord, dorsal and ventral roots, spinal nerves, and dorsal and ventral rami. The dural and arachnoid mater sleeve contain the ventral and dorsal roots and ultimately blend with the spinal nerve epineurium. The spinal nerves are formed by the joining of the ventral and dorsal roots. Each spinal nerve exits the spinal canal through the intervertebral foramen, which is bordered by the uncovertebral joint anteromedially, the zygapophyseal joint posteriorly, and superiorly and inferiorly by the pedicles of the respective vertebral bodies. The most cephalad and first true neural foramen is located at the C2-3 level. This foramen has the largest area, with a progressive reduction in foraminal size observed more caudally (13). The spinal nerve is a mixed nerve that resides within the neural foramen and is accompanied by the radicular arteries and veins (28). The C3 through C7 nerves exit above their respective pedicles, whereas the C8 spinal nerve exits beneath the pedicle of C7. The C1 nerve rests on the posterior arch of C1, where it divides into dorsal and ventral rami, and the C2 nerve exits the thecal sac and descends obliquely across the dorsal aspect of the atlantoaxial joint (29). Upon exiting the intervertebral foramen, the spinal nerves divide into dorsal and ventral rami. The C5-T1 ventral rami contribute to the brachial plexus. The C1-4 ventral rami comprise the cervical plexus, which innervates the cervical musculature and cutaneous structures of the ear, face, and neck. The C1 and C2 ventral rami innervate the atlanto-occipital and atlantoaxial joints, respectively (19).

## AXIAL PAIN AND SYMPTOM REFERRAL

### Epidemiology

Cervical spondylosis describes the degenerative change that affects the five articulations of the cervical segment, including the intervertebral discs, the bilateral zygapophyseal joints, and the uncovertebral joints of Luschka (30). The degenerative cascade is thought to begin with disc desiccation and loss of disc height, which is followed by an approximation of the uncovertebral joints and a disruption of the normal zygapophyseal joint biomechanics. Uncovertebral and zygapophyseal joint hypertrophy, osteophyte formation, anular disruption, and ligamentum flavum hypertrophy can comprise the ensuing phases of degenerative change (31–33). Radiographic evidence of degenerative change is appreciated in 10% of individuals by the age of 25, 35% by age 40, and in up to 95% by the age of 65 (34–36). Plain film imaging in asymptomatic subjects reveals degenerative change affecting the cervical spine in 70% of women and 95% of men between the ages of 60 and 65 (37). It is essential to remember that although there is typical radiographic evidence of degenerative disease, including loss of disc space height and age-dependent osteophytes, in individuals presenting with cervical pain, not

all individuals with degenerative findings are symptomatic (3,37). The incidence of neck pain similarly increases with age, progressing in a fairly linear fashion from age 20 through 60 (3,38). Approximately 95% of individuals will experience cervical pain by the age of 65 (35). Severe episodes of neck discomfort will affect 10% of the population at some point in their lives. The annual incidence of significant cervical pain has been estimated at 12.3% (36).

Referred pain is pain perceived in a region innervated by nerves other than those innervating the true source of the pain. Pain referral patterns arise as the brain is unable to decipher the true pain origin secondary to convergence at the level of the spinal cord and thalamus. Referred pain is typically experienced as deep, diffuse, and poorly localized pain (19). Any of the innervated structures of the cervical spine can contribute to local pain as well as symptom referral. Although injury to the cervical musculature and ligamentous structures can result in local and regional pain (39,40), the intervertebral disc and zygapophyseal joints have been more extensively investigated as pain generators.

### Intervertebral Disc

Degenerative disc disease is most commonly observed at C5-6, with C6-7 involvement the next most prevalent. These intervertebral discs might be more commonly affected because of increased segmental motion at these spinal segments (41,42). An injured disc, resulting from degenerative change or more acute trauma, can produce local and referred symptoms (17). The outer third of the annulus fibrosus houses nerve endings

that can be stimulated during injury. It has been suggested that degenerative or traumatic alteration of the internal architecture of the annulus can result in pain production through stimulation of local mechanoreceptors and nociceptors (17,41). The ability of the annulus to mediate pain has been demonstrated during surgery through mechanical and electrical stimulation of cervical intervertebral discs (42). In addition to this mechanical component of disc injury, discogenic pain might also be biochemical in origin. An annular defect could allow for the migration of nuclear material, which might then stimulate the outer annulus, dura mater, posterior longitudinal ligament, dorsal root ganglion, or spinal nerve (43). Increased levels of inflammatory mediators have been identified in degenerative and herniated discs when compared with asymptomatic controls (44).

Using cervical discography, characteristic discogenic pain patterns have been described (42,45,46). The correlation between cervical disc magnetic resonance imaging (MRI) abnormalities and pain-generating potential observed through discography has been shown to be poor (46). In a study of 807 disc injections, 404 concordant pain responses were used to describe pain referral patterns. Pain referral to the scapular region was observed to arise from disc stimulation at the C3-4 through C7-T1 levels. The C5-6 and more caudal segments were noted to refer symptoms to the upper limb, and C6-7 stimulation was unique in that pain was referred to the anterior chest wall (45) (Fig. 32-5).

### Zygapophyseal Joints

The zygapophyseal joints can also become active pain generators in the setting of degenerative change or following trauma.

**FIGURE 32-5.** Pattern of pain described during cervical discography at each cervical level: C2-3 (A), C3-4 (B), C4-5 (C), C5-6 (D), and C6-7 (E). For illustration purposes only, pain is depicted in a unilateral fashion to the left for C4-5 through C6-7. (From Grubb SA, Kelly CK. Cervical discography: clinical implications from 12 years of experience. *Spine*. 2000;25(11):1382–1389, with permission.)

These posterior elements are particularly vulnerable to injury during a whiplash event. Although often not observed radiographically, zygapophyseal joint fractures, intra-articular hemorrhage, and capsular tears have been observed in pathologic studies (47–53). The prevalence of whiplash-induced zygapophyseal joint pain has been described (54–56). Using diagnostic blocks, chronic cervical zygapophyseal joint pain has an estimated frequency of 54% to 60% (55,56). In this chronic neck pain population, the C2-3 joint has been observed to be most frequently symptomatic, followed by C5-6 (55,56). Of those patients with chronic neck pain, 58% to 88% describe significant headaches (54–56). The prevalence of C2-3 joint-mediated headaches has been estimated at 50% to 53% in those individuals with a chief symptom of headache following whiplash (54,56). The Oc-C1 joints (54,57–59) and C1-2 joints (57,58) have similarly been described as active nociceptors in cervicogenic headaches. Studies in a limited number of asymptomatic and symptomatic volunteers have suggested particular resultant pain patterns from intra-articular zygapophyseal joint stimulation and anesthetization (60–62). Pain arising from C2-3 stimulation was described as referred to the upper neck and occipital region, whereas C3-4 and C4-5 joint pain was observed to affect the mid- and lower cervical region, extending toward the superior scapular border. Pain from C5-6 stimulation was observed to extend toward the shoulder, whereas C6-7 pain radiated over the more caudal scapular region (Fig. 32-6). These degenerative or posttraumatic pain referral patterns arising from primary

**FIGURE 32-6.** Pain patterns described during provocative zygapophyseal joint injection. (From Dwyer A, Aprill C, Bogduk N. Cervical zygapophyseal joint pain patterns 1: a study in normal volunteers. *Spine*. 1990;15(6):453–457, with permission.)

axial zygapophyseal joint or discogenic pain generators can be difficult to distinguish clinically from one another and from radicular pain presenting without a more distal component or neurologic correlate.

A randomized controlled study investigating the therapeutic benefit of intra-articular zygapophyseal joint injections using corticosteroid has suggested that such treatment is ineffective (63). A retrospective uncontrolled study of intra-articular C2-3 joint injection in the treatment of post-traumatic headaches has suggested a significant therapeutic response. A randomized placebo controlled trial of radiofrequency neurotomy in patients with unremitting cervical zygapophyseal joint pain has demonstrated a significant treatment effect (64). Pain is expected to return following neurotomy, as distal axons innervating the zygapophyseal joint are likely to regenerate.

## RADICULOPATHY

### Epidemiology

Cervical radiculopathy can arise from pathologic compressive processes affecting the nerve root, including acute disc herniation, degenerative foraminal stenosis, trauma, or tumor (65). In the 1920s, cervical nerve root compression was described as a cause of anginoid pain (66). Cervical disc herniation resulting in cord compression was initially recognized as a syndrome of spinal cord tumors or chondromas. This syndrome of cord compression was subsequently defined by Mixter and Ayer in 1935 (67) as arising from a ruptured intervertebral disc. In 1936, cervical spondylosis and neural irritation was described as a cause of shoulder girdle and arm pain (68). In the early 1940s, cervical nerve root irritation arising from disc injury was defined (69).

The annual incidence of cervical radicular pain is 5.5/100,000 (70). These injuries represent 5.3% of all nerve root injuries caused by disc pathology. The nerve roots most commonly involved by cervical radiculopathy are C7 and C6, with most studies suggesting C7 syndromes as the most common, followed by radiculopathy of C5 and C8 (65,71–74). Patients younger than 55 years are more likely to present with radiculopathy arising from acute disc herniations, whereas those older than 55 years are more likely to demonstrate symptoms arising from degenerative foraminal or central canal stenosis (30).

### Pathophysiology

The cervical nerve root can be compressed in the neural foramen by the intervertebral disc, degenerative change affecting the zygapophyseal or uncovertebral joint, or in a combined fashion. Cervical radiculopathy arising from a herniated disc is more common than radiculopathy arising from the more slowly evolving degenerative foraminal stenosis typically observed in older individuals (75–78) (Fig. 32-7). Disc herniations have been classified as “soft” and “hard.” “Soft” refers to more acute disc injuries and displacement of nucleus pulposus

**FIGURE 32-7.** T2-weighted axial MRI section at C5-6 demonstrating degenerative spondylosis and resultant advanced right-sided neural foraminal stenosis, delineated by *arrowheads*, in a patient with a C6 radiculopathy.

material, whereas “hard” disc material describes a calcified and spondylotic ridge (72,79,80). With disc degeneration, tears in the annulus can allow for the displacement of the nucleus. Anterior disc herniations are less common as the anterior longitudinal ligament is wider and stronger than the posterior longitudinal ligament (30).

Disc herniations have been characterized based on location (81,82). The three locations described are intraforaminal, posterolateral, and central. Intraforaminal herniations are the most common and may result in an acute radiculopathy affecting the nerve root exiting through the respective foramen. Therefore, an intraforaminal herniation of disc material at the C4-5 level might result in a C5 radiculopathy. The posterolateral disc herniation occurs because the rhomboidal shape of the posterior longitudinal ligament tends to direct disc material to one side or the other. These herniations are located between the lateral edge of the posterior longitudinal ligament

and the posterior aspect of the uncinate process. The central disc herniation passes through the substance of the posterior longitudinal ligament. Such lesions are more likely to result in central canal compromise and spinal cord compression. Central herniations are believed to be more likely to occur in the later stages of cervical degeneration when uncovertebral joint hypertrophy serves as a barrier to the more lateral migration of disc material (83) (Fig. 32-8).

The resultant injury to the nerve roots likely arises from combined mechanical and biochemical pathophysiologic processes. A study in which cervical disc specimens removed surgically from patients with radiculopathy were compared with discs from a traumatic control group found significantly increased levels of matrix metalloproteinase, nitric oxide, prostaglandins, and interleukins in the radiculopathy group (44). These findings, in conjunction with a plethora of literature describing the combined mechanochemical nature of lumbar radicular syndromes, suggest that these biochemical markers are likely involved in the injury process of cervical radiculopathy (84–88).

### Radiologic Findings

Plain films can be used as an initial screening tool but are not necessary in every individual presenting with cervical or radicular pain. In addition to anteroposterior and lateral images, flexion and extension views can prove of value in patients with recent trauma, suspected instability, or in cases of ankylosing spondylitis or RA (65).

MRI is considered the imaging modality of choice in cervical radiculopathy (89). Earlier comparative studies demonstrated a close correlation between findings on cervical MRI, computed tomography (CT) scan, and myelography (90–92). More recent studies have suggested a higher correlation between radiographic and surgical pathology when MRI was used than with either myelography (93) or CT (94). A high incidence of abnormalities has been observed on cervical MRI imaging of asymptomatic individuals. Boden et al. (95) observed significant abnormalities in 19% of 63 asymptomatic patients.

**FIGURE 32-8.** Three locations of focal disc protrusions: **A:** intraforaminal; **B:** posterolateral; and **C:** midline. (From Simpson JM, An HS. Degenerative disc disease of the cervical spine. In: An HS, Simpson JM, eds. *Surgery of the Cervical Spine*. London: Martin Dunitz; 1994:181–194, with permission.)

In those younger than age 40, 14% had a herniated disc or neural foraminal stenosis, and similar abnormalities were observed in 25% of individuals older than age 40 (83). An investigation of cervical myelography has identified nerve root filling defects in 21% of asymptomatic subjects (96).

As there is a significant prevalence of such abnormalities in asymptomatic subjects, advanced cervical spine imaging in symptomatic individuals must be interpreted carefully to determine if a correlation exists between radiographic pathology and clinical findings (97,98). Also of interest is the natural radiographic history of symptomatic disc pathology in the cervical spine. A study following “soft” disc herniations in 21 patients with radiculopathy found that the largest lesions decreased in size the most, with 16 of 21 lesions reducing in size by 35% to 100% at 15-month follow-up CT (99). In similar studies observing patients with serial MRI, 40% to 92% of patients demonstrated radiographic regression (100,101). More lateral and extruded discs were observed to be more likely to resolve (Fig. 32-9).

### Electrodiagnostics

Electromyography (EMG) studies can help to localize the level of a cervical radiculopathy and differentiate such a presentation from a brachial plexopathy, more distal entrapment, or peripheral neuropathic process. Such testing is not necessary in all patients presenting with cervical radicular syndromes. Electrodiagnostic studies might prove particularly useful in individuals with multiple levels of radiographic pathology whose physical examination findings are less conclusive in identifying the segmental pathology of clinical significance. In other cases, a patient might present with clinical findings suggestive of radiculopathy but without a clear radiologic correlate. In these cases, electrodiagnostic studies might similarly prove useful. The earliest abnormality that might be observed in the setting of motor root compromise is reduced voluntary recruitment observed during needle exam. Abnormal activity at rest in the form of positive sharp waves or fibrillation potentials, indicative of axonal loss, might not be observed until at least 18 to 21 days after the onset of a radicular syndrome (102).

**FIGURE 32-9.** Sagittal (A) and successively sliced axial (B) MRI performed 1 month (1M), 3 months (3M), and 5 months (5M) after the onset of a C5 radiculopathy in a 56-year-old man. Radiographic regression of a lateral extrusion with superior and inferior extension is demonstrated. (From Mochida K, Komori H, Okawa A, et al. Regression of cervical disc herniation observed on magnetic resonance images. *Spine*. 1998;23(9):990–997, with permission.)

EMG abnormalities have been shown to correlate well with myelographic abnormalities and operative pathology (103). Needle examination of seven limb muscles is likely adequate for the identification of segmental pathology (104). The segmental sensitivity and specificity of EMG abnormalities might only approach 67% and 50%, and EMG abnormalities can be appreciated at asymptomatic levels (105). The sensitivity and specificity of EMG abnormalities have not been studied against an agreed-upon gold standard. The false-negative rate of electrodiagnostic studies is likely higher than desired (106).

A diagnosis of cervical radiculopathy is established in a patient when corroborative radiographic findings are observed in association with a suggestive pain distribution and/or a myotomal strength deficit, reflex abnormality, or sensory loss. If the cervical radiographs and clinical findings are less conclusive, electrodiagnostic studies might prove helpful in confirming a level of radicular pathology when a myotomal denervation pattern is observed. If radicular pain remains within the differential and these diagnostic criteria are not satisfied, a diagnostic selective nerve root block might be employed. Although the specificity and sensitivity of lumbar diagnostic injections have been described as ranging from 87% to 100% (107,108), the utility of diagnostic selective cervical injections has not been as well-defined (109).

## History

Patients with radiculopathy typically present with a chief report of pain, weakness, paresthesias, or a combination of sensorimotor deficits (65). The majority of patients describe cervical and upper-extremity pain that began without trauma or a particular inciting event (72,73,110). Most studies suggest that pain affects the upper limb more commonly than the neck, although most often both are involved (73,79). Coughing, sneezing, or a Valsalva maneuver may lead to symptomatic worsening. The reports of pain might also incorporate the anterior chest wall, resulting in a syndrome of pseudoangina pectoris (67,111–113). It is often difficult to determine the symptomatic level based on the patient's pain description alone. The distribution of symptoms might not follow the classic dermatomal patterns as defined by Keegan and Garrett (114) or Foerster (115). The limitations of these mapping studies include the assignment of dermatomal distribution based predominantly on the loss of sensation or hyposensitivity arising from compressive injuries. Each of these classic studies describes considerable dermatomal overlap. Dermatomal pain patterns, arising from selective cervical spinal nerve stimulation, have recently been described and may be more representative of the pain and paresthesia patterns clinically observed in radiculopathy (116). Using fluoroscopically guided cervical nerve root stimulation, pain patterns were described after the stimulation of 134 roots in 87 subjects. Some of the highlights of this study included pain distribution distal to the elbow in only 14% of C5 stimulations, C6 affecting the ulnar hand in 67%, C7 uniquely resulting in anterior head symptoms and most commonly referring pain to the chest, and C8 affecting the thumb in 14%. No nerve root pain distribution was observed to be confined

**FIGURE 32-10.** Percent occurrence of symptom provocation for each body map section during C4-7 spinal nerve stimulation. Ventral and dorsal thorax and limb demonstrated. **A:** C4 dynatome; **B:** C5 dynatome; **C:** C6 dynatome; and **D:** C7 dynatome. (From Slipman CW, Plastaras CT, Palmitier RA, et al. Symptom provocation of fluoroscopically guided cervical nerve root stimulation: are dynatome maps identical to dermatomal maps? *Spine*. 1998;23(20):2235–2242, with permission.)

to the classically defined dermatomes in greater than 50% of stimulations (116) (Fig. 32-10). Some of the discrepancy between cervical dynatome and the more classic dermatomal maps might also be explained by intrathecal cervical dorsal root intersegmental anastomosis, which can be present in as many as 61% of individuals (117–119) (Fig. 32-11). Additionally, pain in radiculopathy might arise in part from a myotomal or myalgic pain component arising from ventral nerve root irritation (120).

## Physical Examination

When examining the patient with suspected cervical radiculopathy, it is essential that the clinician remains mindful of extraspinal disorders that can mimic nerve root pathology. A brachial plexopathy or neuralgic amyotrophy with upper-trunk involvement can appear similar to a radiculopathy of C5 or C6 origin (121–123). More localized disorders affecting the upper limb can similarly result in regional pain, including subacromial

**FIGURE 32-11.** Arrows demonstrating ventral (A) and more commonly observed dorsal (B) intradural intersegmental anastomoses between nerve roots of the cervical spine. (From Tanaka N, Fujimoto Y, An HS, et al. The anatomic relation among the nerve roots, intervertebral foramina, and intervertebral discs of the cervical spine. *Spine*. 2000;25(3):286–291, with permission.)

bursitis, lateral epicondylitis, and bicipital tendinitis (65). More distal neural entrapments affecting the median, radial, or ulnar nerve should also be considered. A median neuropathy at the wrist can result in pain extending as proximal as the cervical region (65). When cervical radiculopathy and myelopathy coexist, such as in amyotrophic lateral sclerosis and syringomyelia, the examiner should seek signs of possible combined cord and root compression (65,124).

Muscle girth should be carefully inspected for any evidence of atrophy that might be consistent with a more chronic radiculopathy. Although C5 and C6 involvements can lead to wasting of the biceps and periscapular musculature, loss of triceps girth can be observed in the setting of a C7 radiculopathy. Atrophy of the hand intrinsics might be observed in patients with C8 or T1 pathology. Active cervical range of motion can be recorded and observed for symptom provocation in a particular plane. In particular, extension and ipsilateral side bending are more likely to result in a reproduction of radicular symptoms. Normal range of motion of the neck, using an inclinometer, has been estimated at 60 degrees of flexion, 75 degrees of extension, and 45 and 80 degrees of bilateral side-bending and rotation (125).

Manual muscle testing has been suggested to be a more sensitive means of isolating a level of segmental pathology than either reflex or sensory testing. Variations in the contributions of the spinal nerves to the cords and branches of the brachial plexus can lead to an altered pattern of muscular innervation in the upper limb and perhaps more perplexing motor testing findings (65,74). Reflex testing of the upper extremity should include the bicep, tricep, brachioradialis, and Hoffman's response. Lower-extremity reflex testing should also be included to rule out hyperreflexia or long tract signs. Gait should similarly be observed to rule out ataxia, which might be observed in the setting of cervical cord compromise.

Spurling's maneuver incorporates rotation and side-bending of the head toward the affected side, and this can be combined with axial compression. The goal of this maneuver is to diminish the foraminal area and reproduce radicular symptoms (30). This neck compression test was initially defined by Spurling and Scoville in the 1940s at a time when cervical radicular syndromes were first recognized (126). This maneuver has been demonstrated to have a high specificity but a low sensitivity (110). Such maneuvers should be performed with caution in patients with a suspected radicular syndrome, as this could lead to further neural irritation. In those patients demonstrating a reproduction of radicular symptoms with active cervical extension or ipsilateral side-bending, this provocative test should be avoided (65). The shoulder abduction relief sign has the patient place the affected hand on the top of the head. This position of upper-extremity abduction reduces stress on the nerve root affected by a disc herniation and relieves pain (127,128).

A complete exam should also include passive ranging of the shoulder and impingement maneuvers. Tinel's testing at the supraclavicular fossa, elbow, and wrist and carpal tunnel stress maneuvers, such as Phalen's testing and carpal compression, might reveal a proximal entrapment neuropathy or carpal tunnel syndrome. Observing for a pain response during palpation of the medial and lateral epicondyle can be helpful in ruling out a contributing focal tendonitis. Thoracic outlet maneuvers should also be considered to rule out a contributing lower-trunk plexopathy or dynamic vascular insufficiency, also referred to as "neurogenic" or "vascular" thoracic outlet syndromes. These regional exam techniques are included in the complete examination of a patient with suspected radiculopathy and might enlighten the examiner to a contributing musculoskeletal disorder or more distal neuropathic process.

### Nonsurgical Treatment

Lees and Turner studied 57 patients with a diagnosis of cervical radiculopathy for a period of up to 19 years (35). Patients in this study pursued a variety of treatments, including rest, manipulation, therapeutic exercise, and soft-collar use. Of these 57 patients, 45% described one primary pain episode without a future symptomatic recurrence. Of the remaining patients, 30% described a continuation of mild symptoms, and 25% reported a persistence of significant symptoms or worsening. Of the 57 patients, 32 remained significantly improved, whereas 18 described their condition as static or symptomatic. In their series of patients with radiculopathy, none became myelopathic. Cervical collars appeared to correlate with initial symptomatic relief, but end results were similar among all patients studied.

A review of multiple retrospective and uncontrolled nonsurgical cervical radiculopathy studies revealed satisfactory outcomes in 80% to 90% of patients (73,129,130). Several randomized controlled studies in patients with lumbar syndromes have demonstrated an efficacy of nonsteroidal anti-inflammatory agents and muscle relaxants. Studies investigating the efficacy of oral corticosteroids have been inconclusive (131,132). In a retrospective study of 26 consecutive patients treated nonsurgically, 20 achieved good to excellent results with an average of 2.3 years of follow-up. Oral analgesics, collars, traction, and physical therapy were employed in this treatment group. Twenty-two patients used oral steroids, and nine received epidural injections. Patients with extrusions were noted to fair better than those with contained protrusions (133). In a randomized prospective study, 81 patients were treated with anterior decompressive surgery, physical therapy, or collar use. The surgical group demonstrated significantly greater reductions in pain at 16 weeks, and both the surgical and physical therapy groups demonstrated improved functional abilities as compared with the collar group. No significant difference in outcome as measured by pain and functional profiles was observed between the groups at the final 12-month follow-up evaluation (134). In a prospective study of 155 patients with cervical radiculopathy, one third were treated surgically, whereas two thirds were prescribed medical treatment that included oral analgesics and steroids, traction, and epidural injection. At 1-year follow-up, significant improvements in pain and functional status were observed in both groups, with a greater degree of improvement in the surgical group. Twenty-six percent of the surgical group continued to experience severe pain (135).

Cervical epidural injections can be employed in those individuals with severe pain or symptoms that have failed to respond to an initial trial of spine-specific physical therapy, oral anti-inflammatory agents, and analgesics. A recent prospective, randomized, double-blind, controlled study has demonstrated the efficacy of fluoroscopically guided lumbar transforaminal injections in the treatment of radiculopathy (136). The use of cervical epidural injections has arisen from the described success of therapeutic injections in the treatment of lumbar radicular syndromes. Although controlled trials are lacking, a review of the literature is inconclusive, suggesting good and excellent outcomes ranging from 0% to 69%. Outcomes are typically

better in individuals with radicular as opposed to axial pain, and patients with normal radiographs likely fair worse (137). In a prospective trial of 68 patients with cervical radiculopathy, transforaminal and translaminar epidural injections were employed with 76% of patients describing complete pain relief after 39 months of follow-up (138). In additional uncontrolled prospective studies evaluating the efficacy of transforaminal injections performed with fluoroscopic (139) and CT guidance (140) in patients with cervical radicular pain resistant to prior medical treatment, significant and lasting pain relief was realized without associated procedural complications (Fig. 32-12). In a retrospective study of 20 patients with radicular pain arising from degenerative foraminal stenosis, satisfactory outcomes were realized by 60% of patients with a mean follow-up of 21.2 months (141). A retrospective and uncontrolled study of patients with traumatically induced radiculitis and an absence of radiographic pathology suggests transforaminal injection procedures result in good or excellent outcomes in only 14% (142). In experienced hands, a very low incidence of complications arising from cervical transforaminal injections has been described (143,144). Dedicated reviews (145) have more extensively assessed the literature in terms of therapeutic outcomes and potential complications arising from cervical transforaminal injections. The more recent literature has highlighted rare but catastrophic complications arising from transforaminal injection, in some cases arising from more grossly misplaced needles or ill-advised technique. In other instances, concern has been raised regarding the particulate nature of corticosteroid solutions and the potential for resultant arterial occlusion and infarct of neural tissue (146,147). Ultimately,

**FIGURE 32-12.** Contrast-enhanced left C6 transforaminal selective spinal injection.

additional outcome studies assessing cervical transforaminal injection therapy, and in an injectate specific fashion (148), will be required to further clarify the balance between the potential therapeutic benefits and procedural risks to patients with cervical radicular pain. New injectable medications, beyond the more commonly used corticosteroids and anesthetics, which specifically target particular components of the inflammatory and pain-generating cascade (e.g., tumor necrosis factor or glutamate), might someday be introduced (149,150).

For those patients whose debilitating pain persists despite a full trial of nonsurgical treatments, surgical intervention should be considered. Surgery should be considered without delay in those patients with a pronounced and rapidly progressive neurologic deficit. Significant weakness and weakness, atrophy, and numbness that present without pain are also relative indicators for surgical intervention (106,151).

### Surgical Treatment

Surgical procedures using a posterior approach for cervical spine decompression evolved during the 1940s. Decompression using an anterior approach was described in the late 1950s (152). Anterior cervical discectomy with fusion (ACDF) was initially described by Smith and Robinson (153) as an approach to provide both decompression of the neural elements and stability to the diseased segment. Indications for this approach include progressive or persistent symptoms arising from unilateral or bilateral lateral disc herniations or spondylotic neural foraminal compromise at one to two levels. ACDF is contraindicated in patients with congenital stenosis, stenosis arising predominantly from posterior structures, and disease at greater than three levels (154). The advantages of this approach include the ability to remove anteriorly offending structures without disturbing the cord, resultant neural foraminal distraction, distraction of the segment with an associated reduction in ligamentum flavum buckling, and segmental stabilization (30). Disadvantages of ACDF include graft donor site pain, the need for postprocedural immobilization, the possibility of graft dislodgement, and subsequent adjacent segment degeneration. When used for radiculopathy, ACDF has been described to result in excellent outcomes in 53% to 91% of patients. Multilevel surgery is associated with poorer outcomes (155–158).

Laminoforaminotomy is an alternative and posterior surgical approach to the patient with radiculopathy. This approach is particularly indicated in patients with soft lateral disc herniation or zygapophyseal joint arthrosis who present without significant neck or periscapular pain (30). The advantages with this approach include an avoidance of spinal destabilization, fusion-related complications, and the need for postoperative immobilization (78). Disadvantages include a greater level of postoperative neck pain compared with ACDF during the recovery period and an inability to decompress the cord. This approach is contraindicated in patients with cord compression or cervical kyphosis. Laminoforaminotomy has been associated with 75% to 96% excellent results (159,160). In a study of 846 patients with cervical radiculopathy arising from soft or hard disc material, good to excellent results were observed in 96% (159). An additional study of 170 patients studied postoperatively for

15 years demonstrated a satisfactory result in 86% of patients with a 6% symptomatic recurrence rate (161).

## MYELOPATHY

### Pathophysiology

Disease entities that can present in a similar fashion to cervical myelopathy include motor neuron disease, multiple sclerosis, and other demyelinating conditions, peripheral and entrapment neuropathies, intracranial pathology, spinal cord tumors or syrinxes, and other systemic causes of hyperreflexia (30). Neurologic symptoms of cervical myelopathy can arise during the cervical degenerative cascade from stenotic compromise of the central canal and spinal cord. Similar to findings in the lumbar spine, narrowing of the cervical central canal can arise from developmental abnormalities or acquired change. Cervical spondylosis remains the most common form of central canal compromise and resultant myelopathy. Disc space narrowing leads to a loss of the normal cervical lordosis and buckling of the posteriorly located ligamentum flavum. Combined with flaval buckling, osteophytes from the uncovertebral joints, zygapophyseal joints, and vertebral bodies contribute to the central canal compromise (162). Spinal cord compression arising from spondylosis is typically slowly progressive. Patients are often noted to have significant radiographic compression while remaining asymptomatic. The cord is apparently able to withstand significant chronic deformation without resultant dysfunction (152). In addition to direct compressive effects, dynamic stressors, vascular insufficiency, and ischemia likely contribute to the pathophysiology of myelopathy. In cervical extension, the central canal diameter decreases and the cord may be pinched between the anterior osteophytic vertebral bodies and discs and the hypertrophied posterior elements and ligamentum flavum. During flexion, although the central canal may widen, the cord can become tethered over spondylotic anterior elements (152,163). Instability may also contribute to spinal cord impingement. As spinal segments are stiffened by spondylotic change, adjacent motion segments might also develop relative hypermobility and even subluxation. Myelopathy can also evolve in the setting of ossification of the posterior longitudinal ligament. In ossification of the posterior longitudinal ligament, ligamentous ossification can occur at one or multiple levels. The ossified posterior longitudinal ligament can develop into a bulbous mass that contributes to anterior cord compression. Asian populations, such as the Japanese, have a particularly high incidence of ossification of the posterior longitudinal ligament as compared with other populations. The etiology of this condition remains less clear, but there is likely an associated genetic influence (152).

Pathologic cord findings from myelopathic patients include white and gray matter destruction with demyelinating changes ascending and descending from the site of injury (152,163). An examination of pathologic specimens and correlation with the degree of cord compression has revealed degeneration of the

lateral white matter tracts in mild to moderate compression and necrosis of the central gray matter in more severe compressive injuries. Interestingly, the anterior white columns remain relatively spared, even in more severe cord compression. Histologic changes observed include axonal demyelination followed by cell body necrosis and scarring or gliosis. Cystic cavitation can also be observed within the gray matter. This central destruction is believed to arise from ischemic changes arising from cord deformation (164). Bulging disc material and anteriorly located spurs might also compress the anterior spinal artery, contributing to a vascular myelopathy (152,163). The vascular supply to the gray matter has been shown to arise from arterioles branching from the anterior spinal artery. With compression of the cord in the anterior to posterior plane, these branches are subject to mechanical distortion, which can lead to relative ischemia of the gray and medial white matter (165). Atherosclerosis and intimal fibrosis have also been observed in the regional spinal arteries (152).

The corticospinal tracts are typically involved early in the evolution of myelopathy, resulting in lower-limb weakness. Subsequent posterior column dysfunction results in ataxia manifesting as a wide-based gait (30). A classification system has been proposed that includes five cervical myelopathic syndromes (166). According to this categorization, the most common presentation is the transverse lesion syndrome. In this scenario, the upper limbs are relatively spared with symptoms arising in the lower extremities from corticospinal tract, spinothalamic tract, and posterior column involvement. In the motor system syndrome, symptoms can resemble those of amyotrophic lateral sclerosis. In this scenario, the corticospinal tracts and anterior horn cells are affected by the compressive injury. The patient characteristically presents without sensory symptoms, and upper- and lower-limb weakness can present in combination with spasticity and gait disturbances. The third variant is a central cord syndrome, which is similar to the posttraumatic incomplete spinal cord injury. In these patients, upper-limb involvement predominates, and the prevailing hand weakness has a poor potential for recovery. The upper-limb syndrome of myelopathy has also been described as cervical spondylotic amyotrophy and myelopathy hand (167,168) (Fig. 32-13). In the fourth presentation, Brown-Sequard syndrome, unilateral cord compression and corticospinal tract involvement results in an ipsilateral hemiparesis, and spinothalamic tract compromise results in contralateral sensory disturbances. In the brachialgia cord syndrome, long tract signs present in combination with radicular pain arising from spinal nerve root compression (30,166).

### Radiologic Findings

Although plain radiographs can demonstrate degenerative changes associated with aging and spondylosis, this imaging modality does not offer visualization of the neural elements. When neurologic symptoms are appreciated on exam, they might be localized to the site of pathology appreciated on plain films (169,170). In lateral plain films of patients with cervical spondylosis, anterior osteophytes are often larger than those appreciated posteriorly but typically do not cause symptoms. Posterior

**FIGURE 32-13.** Amyotrophic hand of cervical spondylotic myelopathy. (From Ebara S, Yonenobu K, Fujiwara K, et al. Myelopathy hand characterized by muscle wasting: a different type of myelopathy hand in patients with cervical spondylosis. *Spine*. 1988;13(7):785–791, with permission.)

osteophytes are more clinically relevant because of the possibility of associated neural compression. The presence of such plain film findings should be regarded with caution, as degenerative change is commonly observed in asymptomatic subjects and increases in frequency with increasing age. In some cases, ossification of the posterior longitudinal ligament can be visualized on lateral images as a bar of bone extending along the posterior aspect of the vertebral bodies. Flexion-extension views are necessary to diagnose instability that may not be evident on a neutral lateral view (152). The typical cervical lordosis measures 21 degrees,  $\pm 13$  degrees. Cervical lordosis decreases with age and degenerative change. Additionally, 9% of asymptomatic individuals can demonstrate a cervical kyphosis. The normal adult cervical canal demonstrates a midsagittal diameter of 17 to 18 mm (range from 13 to 20 mm). This measurement is taken from a point at the posterior vertebral body margin to a corresponding point on the lamina line. Cord compromise is believed to occur when the central canal is narrowed to between 10 and 13 mm. At this stage, stenosis is defined as relative. Absolute stenosis is defined by a central canal with an anteroposterior dimension of less than 10 mm. Such canal compromise is highly correlated with spinal cord compression. Cervical extension maneuvers further reduce the canal diameter, and the cord can be dynamically compressed with such maneuvers.

The most accurate means of determining spinal canal dimensions is by CT scan. Ratios have also been described that compare the central canal size to the width of the vertebral body. A ratio of less than 0.85 has been defined as consistent with stenosis, with a ratio of less than 0.8 predisposing the patient to myelopathy. It is believed that such comparisons of vertebral body and canal dimensions are not as reliable in larger individuals (30,37,171–173). MRI is the standard imaging modality in the assessment of patients with cervical myelopathy. The advantages of MRI imaging include superior visualization of the disc and neural elements,

as well as the ability to visualize intrinsic changes within the cord (30). In some instances, in the presence of more long-standing cord compression, cord atrophy might be observed. MRI also allows for identification of parenchymal changes, such as syrinx formation and abnormal signal within the cord, which may be representative of myelomalacia (Fig. 32-14).

Abnormal signal within the cord does not necessarily correlate with clinical outcome, but it does serve to identify pathologic cord change (152). In a recent study that attempted to correlate preoperative cord signal abnormalities with surgical outcome, it was determined that increased T2 cord signal likely represented a wide spectrum of compressive pathology and was therefore not a useful predictor of clinical outcome (174). It has also been suggested that increased T2 signal within the cord with well-defined borders might correlate with a worse outcome than when such T2 signal within the cord is less well-defined and more faint in appearance (175). In a study of 52 patients with mild cervical myelopathy treated nonsurgically and followed for a mean of 3 years, increased T2 signal within the cord was not found to clearly correlate with worse clinical outcomes. In 18% of patients initially observed, increased cord signal was observed to naturally regress over time (176). In patients with significant upper-limb weakness and atrophy, also known as cervical spondylotic amyotrophy, high T2 signal intensity has been observed within the cord in the region of the

**FIGURE 32-14.** Sagittal T2-weighted MRI demonstrating a neutralized lordosis and cord compression from C5-6 to C6-7, with associated increased signal intensity within the cord inferior to the C5-6 disc and posterior to the intervertebral disc space at C6-7. (From Kim DH, Vaccaro AR. Surgical treatment of cervical myelopathy. In: Slipman CS, Derby R, Simeone FA, et al., eds. *Interventional Spine—An Algorithmic Approach*. Philadelphia, PA: Saunders/Elsevier; 2008:753–766.)

**FIGURE 32-15.** Axial T2-weighted MRI at C5-6 demonstrates small areas of high-signal intensity within the spinal cord, inclusive of the regions of the bilateral anterior horn cells. (From Kim DH, Vaccaro AR. Surgical treatment of cervical myelopathy. In: Slipman CS, Derby R, Simeone FA, et al., eds. *Interventional Spine—An Algorithmic Approach*. Philadelphia, PA: Saunders/Elsevier; 2008:753–766.)

anterior horn cells (Fig. 32-15). Such findings suggest that the lower motor neuron component, including upper-limb weakness and atrophy, in these individuals might arise from anterior horn cell damage induced by dynamic cord compression and circulatory compromise (167). The disadvantages of MRI include a more limited visualization of the neural foramen and a relative inability to distinguish between soft and hard disc materials and an ossified posterior longitudinal ligament. Therefore, some practitioners prefer CT myelography, which can offer greater differentiation of soft-tissue and osseous structures in the assessment of patients with cervical disorders (30).

### History

The clinical presentation of myelopathy can be quite variable (177). Patients commonly describe paresthesias, which can occur in a fairly diffuse and nondermatomal distribution in the upper extremities. Many patients are not aware of their weakness but do describe subtle difficulties with balance and gait alteration. As cord compression and myelopathy become moderate to severe, gait and balance difficulties become more pronounced. Fine motor coordination of the hands is adversely affected, with reports of difficulty manipulating buttons or handwriting abnormalities. Patients might report an inability to rapidly open and close the hand (178). Arm weakness may be unilateral or bilateral. Proximal lower-limb weakness usually prevails over a loss of more distal strength. For example,

patients might describe difficulty arising from a chair, but a foot drop would be a more rare presentation. In this regard, cervical myelopathy presents almost oppositely to the weakness associated with lumbar spinal stenosis. Bowel and bladder abnormalities may occur in more severe compressive syndromes, but these are rarer. Although patients will often present with neck pain, as many as 50% will not. As many as 15% of individuals with more advanced myelopathy do not report cervical discomfort, often leading to a delayed diagnosis (152,166,179). Individuals with associated radicular involvement may be more likely to report upper-extremity pain (30).

### Physical Examination

In examining the patient with suspected myelopathy, the neck may be palpated for areas of tenderness. Cervical extension may be restricted and painful for patients with cord or nerve root compression (152). L'Hermitte's sign, initially described in 1932 (180), is performed by passively flexing the neck with the patient in the seated position and causing an electric-type sensation that progresses along the trunk and to the upper and lower limbs. This may be appreciated in 10% of patients with spondylotic myelopathy. A positive response can also be observed in individuals with multiple sclerosis and spinal tumors (166,181). Wasting of the shoulder girdle musculature might be appreciated in patients with stenosis at the C4-6 levels secondary to loss of local anterior horn cell function. Similarly, fasciculations might be noted in the upper-limb musculature. Wasting of the intrinsic hand musculature might be observed (152).

The patient can be asked to hold the fingers extended and adducted. If the two ulnar digits are observed to flex and abduct within 30 to 60 seconds, this is referred to as a finger escape sign, which may be indicative of a myelopathic process. Additionally, the patient should be able to rapidly open and close the hand repetitively up to 20 times in a 10-second interval. A more clumsy performance of this grip-and-release test may also be consistent with cervical cord compression (152). Sensory exam for sharp sensation in the upper and lower extremities can help to demonstrate both diffuse and dermatomal patterns of sensory loss. Vibratory testing, which assesses function of the posterior columns, might demonstrate abnormalities in the setting of more long-standing and severe myelopathy. Reflex testing may reveal hyperreflexia in both the upper and lower limbs. If there is associated cervical root compromise, hyporeflexia might be identified at the respective level in the upper extremities. Long tract signs can be found and include ankle clonus, a Babinski response, and Hoffman's sign. A positive Hoffman's sign is flexion of the thumb or index finger in response to flicking the nail of the index finger (30,182). The inverted radial reflex is another pathologic reflex that can be observed in the setting of myelopathy. Specifically, tapping the brachioradialis tendon results in a hypoactive brachioradialis reflex and hyperactive finger flexion. This is felt to represent cord compromise and a concomitant C5 root lesion resulting in spasticity distal to the level of compression and a hypoactive response at the level of nerve root involvement. In patients with more cephalad cord compromise, at the C3 level or above, a caudally directed tap on the acromion

might result in a scapulohumeral reflex, marked by elevation of the scapula and abduction of the humerus (30,182). Gait should also be assessed for the ability to heel-and-toe walk, as well as heel-to-toe ambulation. Romberg testing, during which the patient stands with the eyes closed and the arms held forward, is a test of position sense. Loss of balance during this exam maneuver may be consistent with posterior column dysfunction (152). If indicated, electrodiagnostic studies might prove helpful in distinguishing a myelopathic presentation from a diagnosis of carpal tunnel syndrome, ulnar nerve entrapment, thoracic outlet syndrome, or a contributing peripheral neuropathy.

### Natural History

Previous studies have described a stepwise and progressive deterioration in patients with cervical myelopathy left untreated (2,183). Lees and Turner (35) observed a natural history of myelopathy, which was rarely rapidly progressive in terms of symptoms and disability. Only 5% of patients demonstrated such deterioration. In this series, 75% reported a stepwise and episodic increase in symptoms. In 20% of patients, symptoms were more slowly progressive. Age greater than 60 years was a poor prognostic factor. Of 15 patients with severe disability from myelopathy, 14 remained severely disabled at long-term follow-up. Nurick (184) studied 56 patients treated nonsurgically for cervical myelopathy over 20 years. He similarly described episodes of symptomatic progression followed by intervals of more static symptoms. In this series, mild myelopathic symptoms carried the best prognosis for a more prolonged course with extended periods of nonprogressive disability. Epstein and Epstein (185) reviewed findings in 114 patients treated nonsurgically and described clinical improvement in 36%, no change in 38%, and worsening in 26%.

Patients with radiologic evidence of cord compression but no signs of myelopathy can be observed and monitored both clinically and radiologically. An exception might be made in a patient with such pronounced cord compression that even minor superimposed trauma could be particularly likely to result in cord injury. Although it might be less likely for such a patient to demonstrate no symptoms of myelopathy, these individuals do at least need to be instructed regarding an avoidance of activities that might lead to a hyperextension-type injury. For those individuals with milder myelopathic symptoms, such as hyperreflexia and more subtle gait abnormalities, the anticipated clinical course suggested by the literature should be reviewed with the patient. If the patient has not demonstrated a progressive deterioration, there may be a role for nonoperative management with neurologic reevaluation every 6 to 12 months (152).

Favorable prognostic indicators include symptoms of less than 1 year's duration, unilateral motor deficits, the presence of L'Hermitte's sign, and a younger age at initial presentation (83).

### Surgical Treatment

Most authors recommend surgical intervention for patients with moderate to severe myelopathy. For patients with similar levels of myelopathic symptoms, operative intervention might be recommended earlier in those individuals with more pronounced radiologic abnormalities, including cord atrophy,

abnormal cord signal, or cervical kyphosis. Surgery is indicated in an attempt to halt further progression of neurologic deficits. The degree of ultimate recovery typically correlates with the severity of preoperative myelopathy. Other positive prognostic factors include larger transverse cord area, younger age, single rather than multiple levels of involvement, and shorter symptom duration (152,179,183).

Both anterior and posterior surgical approaches have been employed in the treatment of cervical myelopathy. Posterior options include multilevel laminectomy, laminectomy with fusion, and laminoplasty. Anterior approaches include single- or multiple-level anterior discectomy with fusion and corpectomy with strut graft fusion. Anterior approaches can be performed with or without anterior instrumentation. The surgical approach to the myelopathic patient is determined by the nature of the central canal compromise and the experience of the treating surgeon. Factors considered in choosing the most appropriate procedure include the number of pathologic levels, the sagittal alignment of the cervical spine, the location of the compressive lesion, and the presence of instability (152).

In the degenerative cervical spine, cord compression typically arises from anterior structures. The anterior surgical approach allows for direct decompression of the thecal sac and cord. If the cord compression arises from protruding disc material at one or two levels, an anterior discectomy with fusion may be performed. If spondylotic disease or ossification of the posterior longitudinal ligament results in compression above or below the disc space, partial or complete resection of the vertebral body may be necessary to achieve adequate anterior decompression.

Bohlman (186) described 17 patients undergoing one or more level ACDF for cervical myelopathy. Two thirds of patients were observed to demonstrate improved ambulation. Fourteen of seventeen had improved upper-limb strength and two thirds improved with regard to ambulation (30,152). A study following 87 patients after anterior decompression for myelopathy described complete motor recovery in 54 patients, partial improvement in 26, no change in 6, and worsening in 1 patient (179).

Patients with more widespread stenosis or cord compression arising from ligamentum flavum buckling may be ideal candidates for a posterior decompressive approach (152). Multiple-level laminectomy may also be indicated in patients with congenital stenosis; stenosis with predominantly posterior compression; or when technical problems, such as obesity, a short neck, or anterior soft-tissue cervical pathology, might interfere with an anterior approach (30). Posterior techniques are more indirect in their effect in that they require the cord to shift posteriorly within the thecal sac to diminish the compression arising from anterior structures. For this to transpire, there needs to be a preoperative straight or preferably lordotic cervical sagittal alignment. A cervical kyphosis will not allow adequate shift of the cord dorsally after posterior decompression. This is an essential determination in deciding between anterior and posterior approaches in the treatment of myelopathy. Multiple-level laminectomy is contraindicated in patients with cervical kyphosis and in children. Laminectomy is specifically contraindicated in children

because of the high risk of postlaminectomy kyphosis deformity. Similarly, if instability is present, laminectomy alone will lead to further destabilization and therefore would need to be performed along with posterior fusion (30,152). When performed with a concomitant fusion, the incidence of postlaminectomy kyphosis may be reduced. The advantages of multiple-level laminectomy include its relative simplicity as opposed to anterior corpectomy as a means of addressing multiple levels of compressive pathology. Additionally, the increased pseudarthrosis rate associated with more extensive anterior fusion procedures can be avoided. Laminoforaminotomy can be added at any level, thereby addressing an associated radiculopathy. The disadvantages of the posterior approach include the associated destabilization of the spine and postoperative kyphosis, which is directly related to the extent of zygapophyseal joint resection performed (187–189). The results of laminectomy procedures for myelopathy do vary considerably, with a review of the literature suggesting a 68% to 85% good or excellent outcome (183,187,190–192).

Laminoplasty was developed by the Japanese to achieve posterior decompression and eliminate postoperative instability and kyphotic deformity by expanding the central canal with retention of the posterior elements (193,194). In this approach, the lamina is opened in a hingelike fashion with the patency of the open-door hinge maintained with either a suture technique or grafting (195,196). A unilateral hinge technique or a midline spinous process splitting with bilateral hinges can be performed (193,197,198). Indications for this approach include developmental stenosis, three or greater level degenerative stenosis, and ossification of the posterior longitudinal ligament (199,200). Contraindications to laminoplasty are similar to those described for multiple-level laminectomy. The advantages of this approach include reduced postoperative instability, zygapophyseal joint preservation, and the avoidance of more extensive anterior fusion procedures. The disadvantages include incomplete decompression, recurrent stenosis, and a higher rate of C5 nerve root palsy (30). A study of 25 patients with myelopathy who underwent laminoplasty demonstrated improved gait in 84%, reduced sensory symptoms affecting the hands in 87%, and improved bowel and bladder function in 77% 18 months following surgery (201). An additional study of patients followed for approximately 13 years after laminoplasty revealed a 75% rate of useful neurologic recovery (202).

## RHEUMATOID ARTHRITIS

Although the cervical spine is commonly affected in patients with RA, the exact incidence of involvement is not clear (203). It has been reported that the radiographic abnormalities in the cervical spine can be observed in 19% to 88% of patients with RA (204,205). Persistent inflammation of the joints of the cervical spine predisposes the patient to eventual structural damage. The primary risk factor for cervical involvement in RA is the severity of the disease, including the presence of erosions, use of steroids, and a positive rheumatoid factor (206,207). The various subluxation syndromes, which may occur in isolation

or combination, arise following damage to cartilage, erosion of bone, and ligamentous laxity (203). Although fatal neurologic complications may occur in rare cases, it appears that cervical spine disease is indirectly associated with higher mortality in RA because it occurs with more aggressive disease (208).

The most common spinal abnormality in RA is anterior atlantoaxial subluxation (AAS), with a reported frequency of 19% to 70% (205). Inflammation of the synovial-lined space between the odontoid and the transverse ligament may result in laxity of the transverse ligament (203). This can result in anterior translation of the C1 vertebra. This displacement can become particularly pronounced during flexion. Using lateral radiographs, separation between the anterior aspect of the odontoid and the posterior inferior tubercle of C1 by greater than 3.0 mm in women and 2.5 mm in men is indicative of AAS (209). Patients with AAS might describe retroorbital, temporal, or occipital pain or an abnormal sensation during neck flexion (203). Myelopathy can arise from compression of the spinal cord between the odontoid and the displaced posterior arch of C1 (203). Vertebrobasilar insufficiency can also arise from AAS, as the vertebral arteries can become kinked around the displaced C1 vertebra with resultant vertigo or more rare instances of impaired consciousness (210). As opposed to anterior displacement, posterior C1-2 subluxation is a rare complication of RA (205). In this subluxation syndrome, erosion of the odontoid is so extensive that the arch of C1 translates posteriorly, potentially compressing the cord.

Vertical displacement of the odontoid into the foramen magnum has been described as cranial settling, vertical subluxation, and atlantoaxial impaction (203). Such displacement can be observed in 3% to 4% of the general RA population and likely occurs in approximately 22% of RA patients with cervical spine involvement (211,212). This translation results from bone erosion, cartilage loss, and eventual collapse of the articulation between the lateral masses of the atlas and occipital condyles and the atlantoaxial articulations. The odontoid migrates superiorly with respect to the Oc and enters the foramen magnum, potentially compressing the medulla (213,214). Projection of the odontoid tip greater than 4.5 mm superior to McGregor's line (the line connecting the most caudal point of the occipital curvature to the dorsal border of the hard palate on lateral radiographs) is consistent with vertical subluxation (203). A myelopathy, or more rarely, life-threatening brainstem compression can result (203,213,214). Lateral or rotatory subluxation of C1 on C2 can result from asymmetric erosion and collapse of the C1-2 articulations. Such subluxation can be defined on anteroposterior plain radiographs if the lateral masses of C1 are displaced greater than 2 mm lateral to the C2 masses (212). Patients with this complication may present with limited head rotation or with the head tilted toward the side of the affected joint (205,215,216).

In 7% to 29% of patients with RA, subluxations occur below the C2 vertebra with C2-3 most commonly affected. Serial subluxation can result in a characteristic "staircase" appearance to the cervical spine (212). These subluxations result from laxity of the longitudinal ligaments and facet joint incompetence. Myelopathy is less common in these cases and only arises

if there is more severe dislocation of a segment or infiltration of the cord by pannus originating from the uncovertebral joints (205,209). Spondylodiscitis is a painful condition that involves erosion of the end plates with loss of disc space height without associated osteophytic change. The pathogenesis of these lesions are unclear but is believed to arise from either primary inflammation arising in the uncovertebral joints (217) or a more traumatic origin in the setting of cervical instability (218,219). Spondylodiscitis may lead to neurologic compromise and can be difficult to distinguish from infection (205).

As neurologic deterioration is less common in milder subluxation syndromes, patients with mild AAS or vertical subluxations and stable neurologic deficits can be managed with careful observation. In more advanced subluxations or with progressive neurologic deficits, the threshold to operate should be reduced, and surgery may be lifesaving in cases of more rapidly progressive neurologic deterioration (206). There is also a role for surgical intervention in patients with advanced subluxation who are stable neurologically but have intractable neck pain (220). In children with juvenile RA, 60% to 70% will eventually demonstrate cervical spine involvement. Although the spinal pathology in these patients can be similar to that in adults, growth disturbances and zygapophyseal joint fusion can also result. Cervical fusion is most commonly observed in patients with systemic or polyarticular disease, and hypoplastic vertebrae can arise at the levels of fusion (221).

## **MECHANICAL INTERVENTION, THERAPEUTIC EXERCISE, AND MODALITIES IN THE TREATMENT OF CERVICAL AXIAL AND RADICULAR PAIN**

Physical therapy and modalities are frequently prescribed for the patient with cervical pain and radicular syndromes. A wide range of therapeutic exercise programs have been employed in the treatment of this patient population. Clinical outcomes can be optimized by proceeding with a comprehensive diagnosis and symptom-specific approach and with the judicious use of modalities when indicated.

To date, there has only been one prospective, randomized, controlled study comparing the outcomes of nonsurgical and surgical treatments of cervical radiculopathy (134). Treatment consisted of an anterior cervical discectomy and fusion without postoperative rehabilitation, 15 individually adapted physical therapy sessions, or 3 months of cervical collar use. Physical therapy protocols were not uniform and could include any of the following: ultrasound, moist heat, massage, cold, manual traction, mobilization, neck and shoulder stretching, isometric strengthening, aerobic exercises, and ergonomic or postural training. This study concluded that long-term results of surgical and nonsurgical treatments for cervical radiculopathy may be no better than the natural disease history alone. Limited conclusions can be derived regarding the efficacy of physical therapy in the treatment of these patients, as treatment was not uniform and protocols were not particularly individualized.

## Mechanical Therapy

The comprehensive mechanical assessment of the patient with a cervical disorder begins with having the patient actively perform repeated end-range movements and sustained positioning in both loaded and unloaded fashion. The performance of end-range movements might identify rapid responders to mechanical therapy and separate slow responders from nonresponders. The results of such movement testing will help both the patient and the treating therapist understand the patient's tolerance of movement and likely positional bias (222). The intertester reliability in interpreting pain location and intensity change (223,224), the effects of repeated movements on symptoms (225,226), and the significance of these findings in predicting the patient's response to treatment (227,228) have received support in current literature. A recent study of patients with discogenic lumbar and extremity pain suggests that a comprehensive mechanical exam may be superior to MRI in identifying symptomatic discs and determining anular competence (229).

Robin A. McKenzie is responsible for developing the mechanical paradigm for the diagnosis and treatment of spinal disorders. This method enables the evaluating clinician to assign a directional preference of motion and instruct the patient in repetitive movements that can decrease spinal pain associated with soft-tissue dysfunctions, structural derangements, or postural syndromes (230). Treatment is based on the individual's signs and symptoms during the movement assessment. Specific spinal motion can affect the patient's baseline symptoms by increasing, decreasing, producing, abolishing, centralizing, or peripheralizing pain. It is also of particular importance to observe whether pain production is evident during a given movement or at end range. Information gathered from the initial mechanical assessment will enable the clinician to categorize patients into one of three different syndromes: postural, dysfunction, or derangement (230).

The postural syndrome is typically seen in younger patients or in individuals with a relatively sedentary occupation or lifestyle. Pain may be isolated to a given region, or cervical, thoracic, and lumbar spine pain can be simultaneously described. Postural syndromes are not associated with constant or referred pain, and repeated end-range movements will not have any effect on symptoms. Postural syndrome pain is reproduced only by sustained positions that are believed to produce tension on relatively healthy spinal tissues that are held at end range. Simply correcting faulty postures can remove such tissue stressors and abolish pain. This positive effect can often be seen on day 1 of treatment. Patients who present with pure postural syndromes should be made aware of the possibility of developing more persistent pain syndromes in the future if these positional issues are not addressed.

Patients presenting with a dysfunction syndrome will invariably have pain provocation when attempting end-range movement in a particular plane. Symptoms are believed to occur at end-range because of the motion restriction caused by mechanically stressing shortened and sensitive spinal tissues demonstrating reduced elasticity. The location of symptoms is always local, with the exception of dysfunctions that similarly

involve the cervical nerve root. When the involved root lacks mobility or glide, a full dermatomal referral of symptoms may occur once the nerve root is similarly stressed. Similar to axial and local dysfunctions, pain produced in nerve root dysfunctions will abolish once the offended tissue is placed on slack. Treatment of this syndrome addresses remodeling and lengthening the adaptively shortened structures. Manual techniques consisting of end-range mobilizations can prove helpful when performed in conjunction with a daily stretching program (230).

The derangement syndrome is the most common and dynamic lesion encountered in the cervical spine. The term *derangement* refers to disrupted or displaced spinal tissue. Although the spinal disc is the most likely tissue to derange, the clinician should be aware that the facet joints, spinal ligaments, and other surrounding soft tissues have the potential to be similarly disrupted. Unique to this syndrome is the phenomenon known as centralization, first described by McKenzie in 1956 (230,231). Repeated end-range movements that cause symptoms to progressively decrease or change from a peripheral to a more central location are considered desirable and should be used as a basis for self-treatment (232). By contrast, movements that appear to increase symptoms or result in a peripheralization of pain should be discouraged (Fig. 32-16).

**FIGURE 32-16.** Each illustration on the left demonstrates centralization of those symptoms depicted on the right. (From McKenzie R. *The Cervical and Thoracic Spine: Mechanical Diagnoses and Therapy*. Waikanae, New Zealand: Spinal Publications; 1990:214–215, with permission.)

The ability to successfully centralize symptoms allows the therapist to treat the patient with the appropriate postural bias, advise the patient to avoid positions that aggravate the condition, and potentially predict a favorable outcome from rehabilitation (233,234). The first goal in the treatment of a derangement syndrome is to reduce the displaced or disrupted tissue. On occasion, specific manual techniques can be performed to expedite the reduction process. Subsequently, the patient is instructed in a specific home exercise program in order to maintain the reduction. Once the derangement is reduced and maintained for at least 3 days, the patient is introduced to progressive spinal loading strategies in order to ensure a proper restoration of motion and function. The final component of treatment includes prophylaxis exercises and providing information to prevent injury recurrence.

In summary, the McKenzie method is a dynamic and individually tailored approach that incorporates the patient's response to a given set of repeated movements or sustained positioning. The most powerful aspects of this paradigm are that it uses readily reproducible treatment strategies and centers the patient as an active participant in the ongoing rehabilitation process. This varies considerably from more passive therapy, which deemphasizes patient education and relies on costly rehabilitation equipment and modalities. The success of this approach is likely to correlate with the level of specialized postgraduate training completed by the treating therapist (235).

### Mobilization

The goal of mobilization is to relieve pain and restore the normal range of motion of the involved soft tissues and joints (236). Mobilizations are often required to facilitate reduction of spinal derangements and can also expedite restoration of motion in spinal dysfunctions. Clinicians should be discouraged from performing spinal mobilization based on palpation techniques used to discern segmental movement. The poor interrater reliability of palpatory assessment techniques in detecting segmental spinal motion has been well documented (237–245). There is evidence to suggest that manual diagnosis techniques may be more reliable if the treating clinician relies on provoking the patient's typical symptoms rather than relying on positional or palpatory findings alone (240,245–249). The therapist should continuously communicate with the patient in order to correlate pain provocation with the direction of mobilizing force and resistance.

Geoffery Maitland has described four grades of passive movement to restore spinal motion (250,251). Grade I mobilizations are performed using small oscillations at the beginning of range of motion. Grade II mobilizations are large oscillations that are performed during resistance-free range of motion. Grade III mobilizations are large oscillations performed at 50% of joint resistance during range of motion. Grade IV mobilizations are described as small oscillations similarly performed at 50% of joint resistance. A plus and minus system is also incorporated into this system to provide a spe-

cific grade of mobilization. Every plus or minus equals 25%; that is, a mobilization graded at 3+ is equivalent to a force of 75% of joint resistance while using large oscillations, and a grade of 3- is equivalent to a force of 25% of joint resistance while using large oscillations.

Mobilization with movement, natural apophyseal glides, and sustained natural apophyseal glides described by Brian Mulligan are other categories of mobilization that are quickly gaining popularity in field of manual rehabilitation therapy (252). Further clinical investigations will help to clarify the utility of manual therapy in the treatment of patients with cervical disorders.

### Manipulation

Manipulation is a passive movement that is applied to a joint or structure beyond normal physiologic limits with the intent of improving range of motion or reducing a derangement (253). Some believe that manipulative procedures to the zygapophyseal joints enhance afferent signals from mechanoreceptors to the peripheral and central nervous system (254). This normalization of afferent impulses is hypothesized to reduce muscle guarding, improve muscle tone and local tissue metabolism, and lead to increased range of motion and pain reduction (235). Before performing spinal manipulation, the clinician must rule out cervical instability and vertebral artery insufficiency, as high-velocity movements could place the patient at risk for neurologic compromise or vascular insult (255). Manipulation should also likely be avoided in patients with radicular pathology or significant neural foraminal or central canal compromise. It is also recommended that spinal manipulation only be performed by skilled clinicians with comprehensive understanding of spinal disorders.

Although spinal manipulation appears to lead to short-term benefits and may be effective following an acute injury (256–258), several reviews of the manipulation literature have concluded that there are not enough positive studies of acceptable quality to support spinal manipulation as any more efficacious than other treatments (257,259,260). Similarly, there is no evidence that manipulation provides long-term relief, improves chronic conditions, or alters the natural course of the disorder being treated (253,261,262).

### Collars

Soft cervical collars are often prescribed for the patient with acute cervical pain or radiculopathy. Soft collars may serve as a postural cue but do not restrict motion (263,264). If prescribed with the narrow end worn anteriorly, these collars might help to restrict cervical extension in the patient with radicular pain. By introducing relative cervical flexion, such use might prove helpful for the patient with radiculopathy while resting supine and during evening hours. More rigid cervical collars do offer true flexion and extension motion restriction and can be used in the patient with suspected instability (265). In a study of patients prescribed more rigid collars, patient compliance with their use was approximately 70% (266). Although soft cervical collars can improve patient comfort, long-term clinical outcomes

are likely not affected by collar use (267,268). In the absence of significant instability, it has been recommended that collars not be used continually for greater than 72 hours because their use can lead to soft tissue tightening and a delay in range-of-motion restoration (268–270).

### Modalities

The clinician should limit the application of modalities to the acute injury phase with a primary objective of pain modification. Both superficial heat and ice have the potential to serve as an analgesic and reduce muscle spasm. Neural firing rates have been demonstrated to change in response to changes in temperature (271). Both an elevation and a reduction of muscle temperature resulting from the application of superficial heat and cold have been correlated with decreased gamma motor neuron activity (272,273). These changes in nerve firing rates are thought to contribute to a reduction in muscle spasm (274). Although superficial heat is often applied for comfort measures, application of ice is preferred in the acute phase of injury because of its greater depth of penetration and its analgesic and anti-inflammatory effects (235). Local regular icing can result in vasoconstriction and a reduction in the release of nociceptive and inflammatory mediators such as prostaglandins (275). The use of heat or icing modalities can be repeated several times daily. The decision to use heat or ice can be predominantly determined by which is perceived by the patient as most analgesic.

Ultrasound is probably one of the most commonly overused physical therapy modalities. A review of 35 randomized controlled trials published between 1975 and 1999 studying the effectiveness of therapeutic ultrasound revealed that there was little evidence that active therapeutic ultrasound was more effective than placebo in treating people with pain arising from a wide range of musculoskeletal injuries or for promoting soft-tissue healing (276). Electric stimulation consisting of both low- and high-rate transcutaneous electrical nerve stimulation and interferential current is often similarly used in an effort to reduce pain and inflammation. Uncontrolled studies have suggested a benefit from electrical stimulation use in patients with cervical radicular pain (277). The use of modalities in the treatment of cervical and radicular disorders should be time limited and should not serve as a substitute for a more active rehabilitation approach.

### Traction

Traction is often used in patients presenting with cervical radiculopathy. The literature is lacking a prospective, randomized, controlled study comparing traction with other rehabilitation approaches in the treatment of radiculopathy, and the efficacy of traction in improving treatment outcomes has not been demonstrated (278–282). A reduction in the signs and symptoms associated with spinal nerve root impingement has been reported with traction use, particularly if applied shortly after the onset of radicular pain (283). In a study of patients with whiplash symptoms, improved cervical spine range of motion was initially observed but with no change in eventual

symptomatic outcome (284). It has been suggested that if a sufficient traction force is applied, the size of the neural foramen may temporarily be increased, reducing pressure on a spinal nerve root and potentially contributing to the healing process (285–287). The clinician is encouraged to apply manual traction to assess the likely therapeutic response to force before introducing mechanical devices. The application of traction might only be considered in those patients unable to reduce radicular symptoms through more independent mechanical exercises.

Maximum posterior elongation of the cervical spine is achieved during traction when the neck and angle of pull are in a position of 24 degrees of flexion (288). Over-the-door traction units are properly used with the patient facing the door with 20 to 30 degrees of neck flexion (288,289). Home traction devices have also been designed to apply cervical distractive forces in the recumbent position, and these might allow for more secure and reproducible patient positioning. Mechanical traction may be administered statically, with a uniform force throughout the treatment session, or intermittently, with the force varying throughout the session. It is generally recommended that static traction be performed if the area being treated is more acutely inflamed, if the patient's symptoms are easily aggravated by motion, or if the patient's symptoms are related to disc protrusion (290). The force of traction should always be kept low during the initial traction session in order to decrease the risk of reactive muscle guarding and to further confirm if mechanical traction is appropriate. The recommended initial mechanical force for cervical traction is between 8 and 10 lb (271). Fifteen pounds of force will introduce muscle stretching, whereas 25 lb of force is the minimum force required to achieve vertebral separation. Cervical traction has been demonstrated to result in greater vertebral distraction with a 50-lb than with a 30-lb force. When used with a 24-degree angle of pull, no significant difference in vertebral separation is noted after 7, 30, or 60 seconds of force applied (289). With a 30-lb force applied for 7 seconds with alternating rest periods of 5 seconds, maximal vertebral body separation has been observed after 25 minutes of use with a resolution of vertebral body positioning after 20 minutes of traction termination (291). Nerve root function should be evaluated before and after the application of this modality. Traction use is contraindicated in patients with myelopathy, instability, and RA and should be introduced with caution in elderly patients who may be at greater risk for vascular injury (291,292).

### Stabilization

Currently, there is no available literature regarding the efficacy of cervicothoracic stabilization programs in the treatment of axial pain or radicular disorders, but a recent study of lumbar stabilization prescribed in a diagnosis-specific fashion demonstrated a resultant reduction in pain and functional disability (293). O'Sullivan et al. have demonstrated functional gains from training the transversus abdominus muscle and the implementation of a lumbar spinal stabilization program

in patients with degenerative lumbar disease. One of the innovators of the stabilization program used in the O'Sullivan study, Gwedd Jull of Australia, has recommended a similar treatment approach for cervical spine disorders consisting of strengthening exercises for the deep neck flexors and scapular stabilizers. To isolate the deep cervical flexors, investigators have suggested the use of a pressure-sensor device to provide visual biofeedback to the patient as controlled cervical flexion from neutral is performed (295).

The combined goal of stabilization is to introduce sound postural strategies, improve the strength of the regional musculature, and restore pain-free range of motion. Cervicothoracic stabilization incorporates strengthening of both the neck and the upper-quarter musculature. Special emphasis should be placed on training the scapular retractors and depressors. While performing stabilization exercises, the patient is instructed to maintain a neutral spine position. This can be reinforced through visual feedback with a mirror or verbal feedback from the treating therapist. Optimal stabilization training of the cervicothoracic region is achieved by also incorporating the lumbar spine and lower extremities (296). The lumbar spine and lower-extremity musculature provide the essential foundation for the cervicothoracic region and should not be ignored during a comprehensive stabilization program.

### Work Ergonomics

Instruction in proper positioning at the work station represents an important component in the rehabilitation of patients with cervical disorders. Regardless of the therapeutic exercise program employed or the patient's diligence with home exercise efforts, sustained spinal posturing out of the neutral zone can lead to further aggravation of the affected tissues and a perpetuation of symptoms. The sedentary worker spending most of the day seated at a desk is more likely to encounter proper positioning challenges. In general, the patient should be instructed to avoid, whenever possible, those positions that typically aggravate his or her cervical or limb pain. The recommended positioning at the desk or computer station is usually prescribed with approximately 90 degrees of hip, knee, and elbow flexion (295) (Fig. 32-17). Proper distance from the computer monitor is an arm's length measurement, which is unique to each individual. The upper third of the computer screen should be situated at eye level. Prolonged phone use can also serve as a cervical stressor as ipsilateral neck flexion is typically performed while using the telephone. Headset use can help eliminate this provocative position (297). Individuals that require bifocal eyeglasses should be instructed to position reading materials in such a fashion as to avoid sustained cervical extension postures (298). In addition, the wrist or elbow, and preferably both, should be maintained in a supported position. This support contributes to total neutral positioning of the body and ultimately can lead to decreased stresses on peripheral nerves passing through the elbow and carpal tunnel.

**FIGURE 32-17.** Correct ergonomic positioning.

### Massage

In cases in which debilitating muscle guarding or soft-tissue pain persists despite the application of mechanical exercises or manual techniques, soft-tissue massage may prove helpful. A study evaluating the benefits from soft-tissue massage in patients with chronic tension headaches suggests a resultant reduction in pain scores and frequency of neck pain events (299). A more recent systematic review of massage employed for lumbar pain identified four randomized clinical trials in which massage was used as the sole treatment modality. This review concluded that massage appears to have some efficacy as a therapy for low-back pain. The author of this review emphasized the methodological limitations in the massage literature and the need for more well-designed clinical trials. The use of massage should likely be limited to the more acute injury phase, with an emphasis placed on graduating the patient to a more independent and mechanical approach to addressing the underlying symptom generator.

### The Physical Therapy Prescription

The physical therapy prescription should mark the initiation of an ongoing dialogue between the physician and the therapist. Its purpose is to introduce the patient to the treating therapist and provide the therapist with pertinent physical and radiologic findings. As the relationship between the physician and the therapist matures, physical therapy prescriptions do not need to be extremely detailed. The prescribing physician should, whenever possible, avoid the assignment of more generic diagnoses, that is "sprain/strain," and treatment recommendations. Although the astute spine therapist, through a comprehensive initial evaluation, will often be able

to appropriately design the rehabilitation program, information provided by the physician can be vital in selecting treatment strategies, maintaining precautions, and optimizing outcomes.

# Rehabilitation of Lumbar Spine Disorders: An Evidence-Based Clinical Practice Approach

## INTRODUCTION

The approach to low back pain (LBP) has changed dramatically in the past decades, while medicine has changed also (1–4). Formerly, according to a classical disease model, all LBP classifications considered a pathoanatomic basis and consequently proposed treatments; but the increasing burden on society in terms of costs and disability (5), presumably due to inappropriate treatment and medical approach, lead to a revolution in the understanding of the problem (4,6). Accordingly, LBP is now classified as secondary (<10% of cases) and primary, or idiopathic, or simply LBP; the latter is then divided according to the localization of symptoms (LBP and sciatica) and the duration of pain (acute, subacute, and chronic) (3,7–11). Generally speaking, in this model LBP is recognized as a biopsychosocial syndrome (4,12). Consequently, the importance of the discipline of Physical and Rehabilitation Medicine (PRM), as one with particular focus on biopsychosocial approaches according to the International Classification of Functioning (ICF) (13–20), has greatly increased in this field (21,22). As is always the case in medicine, these advancements require time to reach the clinical everyday world (10,23–27). Today the clinical reality is a mix of different approaches, usually driven by what each single specialty, doctor, and/or allied professional knows and offers in terms of treatments, more than by a coherent and systematic evidence-based approach (28,29). Considering the world of PRM and its inevitably multi-professional reality (14,30), combined with the almost complete outpatient reality of LBP treatment, the confusion seems even higher than in other specialties (31–35). Moreover, considering the widespread recognition of LBP as a biopsychosocial syndrome, and consequently the crucial role PRM should have in its treatment, this confusion must be cleared away. That is the main aim of this chapter.

This chapter is fully evidence-based, but it is also totally focused on what to do in the clinical everyday world once the evidence is known: in reality it is an evidence-based clinical practice tool. Therefore, we will start from some clinical-scientific premises, including assessment and outcome criteria, the actual scientific evidence on treatments of PRM interest,

and also the diagnostic-therapeutic pathways (flowcharts) (9) to be followed. In fact, another unavoidable premise is that in LBP rehabilitation, as well as in all other PRM approaches to patients who are diagnosed with a specific disease, a correct disease diagnosis is the first step and must be achieved. We cannot rehabilitate the patient if we do not start with diagnosis, and only after that can we look for a mandatory biopsychosocial picture of the patient, possibly inside the mainframe of ICF (17,18,36–38). Finally, we will have an evidence-based description of the single clinical LBP pictures of PRM interest, concluding with the rehabilitation approach to each of them.

The last important premise is one of terminology: rehabilitation is neither a pain-orientated (PO) nor a conservative treatment. From our perspective, the term “conservative treatment” should be abandoned because it is based on the past, when the only need was to define whether a LBP was surgical or not (21,22). The term “conservative” is not the positive affirmation of what we have to be in regard to our patients. Instead it is only the negation of surgery, as if this were the gold standard. In the so-called field of conservative treatment there are abundant treatments that focus on pain (“PO treatments”); these have been traditionally used for years, and continue to be used, sometimes according to some evidence. However, with the increased scientific understanding of the limits of this PO approach (4,5,39), more complex rehabilitation approaches focusing on increasing function, on recovering activities and participation, and on rising quality of life have emerged and developed: we will call them functioning-orientated (FO) approaches (40–42). These FO approaches are based on WHO’s understanding of functioning (13), representing the comprehensive view taken by PRM (14–20,30). In most patients this is far more appropriate, and it should be the main concern of PRM specialists, who have the best conceptual tools with which to appropriately rehabilitate LBP patients (13,14,22,30,37,38). This does not lead us to ignore PO treatments, which in some or many cases must be applied, but the differentiation is crucial to achieving a better understanding of our everyday behaviors, including their advantages and limitations.

## ASSESSMENT, DECISION-MAKING PROCESS, AND REHABILITATION TREATMENT TOOLS

### Assessment and Outcome Criteria

An appropriate diagnostic workup is the cornerstone of an effective treatment. It is founded on taking the most accurate medical history and conducting a thorough physical examination (8–10), both of which are useful in forging a good doctor-patient relationship. The first objective of assessing the patient who is experiencing back pain is to identify the patient who presents serious spinal pathology. It is possible to establish a well-defined pathology in only about 15% of patients who present LBP (43). Among patients suffering from LBP and sciatica for a period of approximately 4 weeks, Deyo et al., as well as Udén, were able to identify the following: herniated disc (4% to 5%); lumbar spinal stenosis (LSS) (4% to 5%); spinal fractures (4%), metastatic tumor or osteomyelitis (1%); and visceral pathologies such as aortic aneurysms, kidney, or gynecological disorders (<1%).

According to Waddell (44), when dealing with a patient suffering from LBP, the first step is to identify any possible serious spinal pathologies (primitive or metastatic neoplasia, infections or inflammatory diseases such as ankylosing spondylitis, osteoporotic fractures, cauda equina syndrome, or any of various neurologic diseases). An assessment of the pain is then conducted in order to determine whether it originates in the nerve root (sciatica from a prolapsed disc, spinal stenosis, or surgical scarring):

- On one side of one of the lower limbs, generally radiating below the knee, down to the ankle and the foot
- Very often more intense than LBP
- Hypoesthesia or paraesthesia with the same distribution
- Positive signs of radicular irritation
- Motor, sensory, or reflex changes related to a single nerve root

Assessing LBP means evaluating pain symptoms, with all the ensuing uncertainties that this entails. It is especially difficult to objectively assess the severity of the pain due to the complex neurophysiologic sensory mechanisms and the psychoemotional assimilation that occurs in the experience of pain, and which cannot be differentiated by the person experiencing it (45). Regarding duration of the pain, the updated universally accepted classification is (3,5,8,11,46):

- Acute LBP (ALBP): up to 4 weeks
- Chronic LBP (CLBP): over 6 months
- Subacute LBP (SALBP): from 2 to 6 months

A recent study has shown the presumable transition between ALBP and SALBP in 14 days (47), while others propose 90 days as the starting point of CLBP (9). As the symptoms of pain persist, there is a shift from a pathology of a physiological nature with biological ramifications to one characterized by psychosocial implications. The assessment at this stage no longer simply concerns a disorder but also disability and diminished quality of life.

### Scientific Evidence on Assessment

Generally in the medical field, the basic requirements for any diagnostic test are its accuracy, safety, and reproducibility (48–50). Accuracy comprises the twin parameters of specificity and sensitivity: specificity refers to the ability of the test to be positive only when a pathology is present, while sensitivity is the characteristic of being positive whenever the pathology is present. Moreover, in order to ascertain the accuracy of a diagnostic test it is necessary to have a gold standard against which to measure the sensitivity and specificity. For spinal pathologies, in some cases the gold standard is the presence or absence of defined tissue pathology confirmed through a surgical procedure, while in other instances it is the confirmation or relief of pain. In all these cases, given the difficulty in obtaining an objective assessment of pain, the true accuracy of any test that provokes or alleviates pain carries an intrinsic uncertainty (51).

Various clinical guidelines (CGs) (8,9,52) stress the importance of taking a detailed medical history and a comprehensive physical examination of the patient, and they emphasize that during the first visit in particular, the physicians should dedicate their full attention to the patient and spend the appropriate amount of time needed to earn the individual's trust. Indeed, evidence shows that an appropriate clinical approach can only have a beneficial impact on the pain and on allaying the patient's fears (53).

Due to its biopsychosocial characteristics, an important future advancement in LBP assessment could be represented in the near future by the application of the ICF (15–20) and mainly its core set (36–38,54–56).

### Red and Yellow Flags

To improve the accuracy of excluding serious spinal pathologies, as well as to reassure the patient, almost all existing CGs (8,9,52) have recommended that a series of risk factors called “red flags” (Table 33-1) be assessed as the patient's medical history is taken down. The presence of one or more of these flags would determine whether there is a need for a targeted diagnostic confirmation and subsequent consultation with a specialist. Deyo has shown that red flags have a high degree of sensitivity for excluding a cancerous pathology among 2,000 patients with LBP (57).

Other CGs (58) have identified other risk factors, being indicators of the possible evolution in chronicity of pain, that have been called “yellow flags” (58,59), whose presence, if found in ALBP or SALBP, indicate the need to take into account psychosocial factors and apply early therapeutic strategies in a cognitive behavioral approach (see Table 33-1).

### Medical History and Physical Examination

The meta-analysis of van den Hoogen et al. (60) does not allow the drawing of definitive conclusions on the accuracy of medical history-taking, the physical examination, and the assessment of a Visual Analogue Scale (VAS), notably due to inadequacies in the methodologies of the primary studies, particularly regarding referral bias. However, there is agreement

**TABLE 33.1** In the Diagnostic Process of LBP Patients It Is Important Since the Beginning to Search for Red Flags (Risk Factors for Secondary LBP Due to Important Pathologies): In Subacute Cases It Is Crucial to Search for Yellow Flags (Risk Factors for Chronicization of LBP) (9)

**Red flags (Risk Factors for Secondary LBP Due to Important Pathologies)**

Back pain in children <18 y with considerable pain or onset >55 y  
 History of violent trauma  
 Mild trauma in an aged patient  
 Constant progressive pain at night  
 History of cancer  
 Systemic steroids  
 Drug abuse, human immunodeficiency virus infection  
 Weight loss  
 Systemic illness  
 Persisting severe restriction of motion  
 Intense pain or minimal motion  
 Structural deformity  
 Difficulty with micturition  
 Loss of anal sphincter tone or fecal incontinence; saddle anesthesia  
 Widespread progressive motor weakness or gait disturbance  
 Inflammatory disorders (ankylosing spondylitis) suspected  
 Gradual onset <40 y  
 Marked morning stiffness  
 Persisting limitation of motion  
 Peripheral joint involvement  
 Iritis, skin rashes, colitis, urethral discharge  
 Family history

**Yellow Flags (Risk Factors for Chronicization of Acute and SALBP)**

Personal	Age (U form correlation) Female gender Minor ethnicity Low income Low education
Medical	High BMI Previous surgery Impairment Neurological deficit Radicular impingement (SLR, Wassermann tests)
Pain related	Duration Intensity Leg pain Pain in lateral flexion and/or in flexion-extension Difficulties in sitting
Impairment disability related	High referred impairment High functional limitation at 4 wk High disability (Roland-Morris, Oswestry, Sickness Impact Profile) Perceived risk of not recovering
Psychosocial	Not appropriate signs and symptoms Avoidance behavior Psychological burden Vital energy reduction Reduced emotional confronting capacity Social isolation Depression (SCL-90, Zung, Beck Depression Inventory) Somatization (SCL-90) Reduced coping strategies (CPCT)

on the validity of medical history and physical examination to gather the red flags to detect conditions such as cancer, cauda equina syndrome, spinal stenosis, ankylosing spondylitis, or spinal deterioration due to osteoporosis.

Several studies have focused on how a physical examination is performed in regard to the range of motion of the lumbar spine, muscle strength, and provoking or relieving pain symptoms with specific movements. The McKenzie technique for determining which movements can cause the centralization of pain and what courses to take has not found unanimity in the literature for indicating prognosis. While positive findings have been reported in Long and Donelson (61,62), other authors have yet to establish a clear clinical benefit (63).

A study by Simmonds et al. (64) has established the reliability, validity, and good clinical use of nine physical evaluations comparing asymptomatic subjects and LBP patients. Also, a modest correlation with the degree of disability was detected through a questionnaire. No evidence of clinical benefit has been obtained in the analysis of muscle strength carried out by various machines (65). In fact, a good correlation of testing and retesting has shown that the Biering-Sørensen test is simpler to conduct and is of greater benefit in clinical practice (66). Regarding muscle fatigue, Taimela et al. (67) have shown that LBP sufferers first get tired, whereupon the fatigue reduces the quality of movement, and consequently the muscle fatigue lessens the kinesthesia. Muscle fatigue, therefore, is a risk factor.

Clinical trials, as well as various national CGs, have taught us that a fundamental point of the evaluation is physical contact with the patient: palpation of the vertebral structure provoking pain and the direct assessment of regional and segment motion are an integral part of a complete physical examination. The analysis of literature in this area by Seffinger et al. (68) shows that the most reliable tests are those that provoke pain, while less reliable diagnostic testing is that which is done by palpating the soft tissues. Regional motion testing is also more reliable than segmental motion testing, and intra-examiner reliability is greater than inter-examiner reliability.

If, on the one hand, there is a lack of definition of the specific structural causes in a great number of LBP sufferers, on

the other hand the practice tends to identify specific subgroups of subjects affected by LBP. Many consider lumbar instability to be one such subgroup. In this regard, a recent study (69) has examined predictive clinical indicators of instability, the gold standard being x-rays in the flexed and extended positions. A positive correlation was observed in the concurrent presence of hypermobility in the intervertebral motion test and the range of the lumbar flexion greater than 53 degrees (LR 12.8).

### ***LBP and Leg Pain***

Regarding the pain that radiates to a lower limb below the knee and the probable correlation with the presence of a herniated disc, scientific evidence (70,71) generally refers to secondary or tertiary health care settings, the gold standard being the presence of a herniated disc confirmed by surgery. Therefore, it is most likely that only the more serious cases are being reported instead of cases of patients seeking primary care. Based on these studies, the distribution of pain seems to be the only sensitive symptom, while paresis and sensory deficits seem neither sensitive nor specific. Among the indicators, the depression of reflexes is not sensitive and straight-leg raising (SLR) seems to be an indicator of sensitivity (but of low specificity), while the crossed SLR has less sensitivity but a higher specificity. The positive presence of both suggests a better clinical indication of a herniated disc.

Concerning a prospective study of 105 patients (72), the strongest indicators of a herniated disc among the 25 clinical variables (the gold standard being the computer tomography [CT] and/or magnetic resonance imaging [MRI] scan) were the range of lumbar motion in forward flexion and the distribution of pain in the lumbar extension while in the standing position. Patients with herniated discs had significantly less mobility during forward flexion but a higher distribution of pain to the leg during a lumbar extension (Table 33-2).

### ***Diagnostic Imaging***

The choice of an imaging examination for diagnostic purposes should only be based on an evaluation of the symptoms, medical history-taking, and physical examination. The purpose of diagnostic imaging is to verify the suspicion of a serious

**TABLE 33.2** Findings in Patients with History of Well Described Lumbar Nerve Root Pain of Sufficient Predictive Value for Finding a Disc Hernia at Neuroradiographic Examination (9)

Finding	Prediction Strength
Crossed SLR reproducing pain in the symptomatic leg	+++
SLR <60 degrees (SLR reproduces leg pain)	++
Ankle dorsiflexion weakness	+
Great toe weakness	+
Impaired ankle reflex	+
Sensory loss, pins and needles, paresthesia	+
Patellar reflex weakness	+
Ankle reflex weakness	+
Severe radicular pain	++

Pain drawing (exact dermatome depicted)	(+)

pathology due to red flags, or a herniated disc due to symptoms ascribed to nerve-root pain. In the case of LBP or simple sciatica, and in the absence of red flags, diagnostic imaging is not required within 30 days of the onset of symptoms (3,8,9).

Regarding x-ray examinations, all the current CGs agree on refuting their diagnostic or therapeutic value in the absence of red flags and discourage any routine use. van Tulder et al. (73) have noted that the only x-ray anomaly that could be linked to LBP is disc deterioration (odds ratio 1.2:3.39). However, due to inadequate methodologies in primary studies this conclusion cannot be considered definitive. Consequently, the authors claim that “no firm evidence exists for the presence or the absence of an association between x-ray findings and nonspecific LBP” (Table 33-3).

**TABLE 33.3** Studies on the Association Between Radiographic Findings and Non-specific LBP Judged to be Valid (9)

Radiographic Finding	No. of Studies	Odds Ratio	Results
Disc degeneration	12	1.2–3.3	Moderately positive
Spondylosis	3	1.2–2.0	Negative
Spondilolysis and spondilolisthesis	6	0.82–1	Negative
Spina bifida	2	0.5–0.6	Negative
Transitional vertebrae	3	0.5–0.8	Negative
Scheuermann disease	2	0.8–3.6	Unclear

The noninvasiveness and characteristics unique to MRI in satisfactorily evaluating both soft and bone tissues allow it to be a more comprehensive tool for the diagnostic imaging of an LBP patient. That being said, there is no evidence that its use provides any real advantage in the treatment of simple LBP (74,75). Many studies have shown that the presence of disc anomalies (bulges, swelling, hernia) in the vertebral canal, the foramen, and the vertebral structures are found in asymptomatic subjects. Consequently, Roland and van Tulder (76) recommended, somewhat provocatively, that radiologists add the following to the reports along with their referrals: “This finding may be unrelated to patient symptoms because it is often seen in asymptomatic subjects.” The MRI is a highly sensitive exam, and hence there is a risk of obtaining many false positives. We must bear this in mind in clinical practice so that costs can be kept down and unnecessary surgical procedures avoided.

### *Psychosocial Factors, Disability, and Quality of Life*

The assessment of a patient with LBP must not be limited to a physical examination but should also include an analysis of psychosocial factors that play a crucial role in the chronicity of pain, delays in returning to work, and the success of the treatment. Evidence shows that some conditions—such as low level of job satisfaction, poor work motivation, disability compensation, dissatisfaction with previous treatment—are risk factors for chronicity and/or the relapse of LBP. Regarding psychological factors as chronicity/disability predictors, a recent review (77) has examined the role of psychological discomfort and depression (Zung scale), and somatization, while less evidence was attributed to cognitive factors such as catastrophism. However, although the symptoms of mental stress in asymptomatic subjects can be predictors (78), the main indicator for LBP is a positive medical history (79).

Persistent pain always entails a certain degree of disability. The measurement for disability in LBP can be gauged through means of dedicated and scientifically validated questionnaires such as the Oswestry LBP Disability Questionnaire and the Roland-Morris Questionnaire (80–83). A recent study (84) has correlated pain (VAS), disability (Oswestry Questionnaire), and the quality of life (EuroQoL) in LBP patients. The data have shown a weak but significant correlation among the three elements. Thus, it appears that the persistence of pain and disability worsen the quality of life to an appreciable extent. Clearly, the impact of pain and disability on decreasing the quality of life depends more on their duration than their intensity. Moreover, even a clinically significant variation in the degree of pain can bring about nearly imperceptible changes in disability and quality of life. We must, therefore, adopt the concept of the minimal clinically important difference (85,86), that is, the slightest change in an evaluation scale that will be perceived by the patient as an improvement in his or her condition. It is important to stress the benefit of such a concept as a better outcome criterion because it is aimed at the patient from a functional and psychosocial perspective. However, it is a well-known fact that today there is also the need

to evaluate a treatment's efficiency in terms of managing the costs of health care.

This section concludes with a word about younger patients: The findings of more recent studies show there is an increased incidence of LBP among children and adolescents. Among the defined risk factors in a school population of 10,000 subjects are the excessive weight of backpacks, the sitting level of students compared to that of the teacher, and the heights of chairs and desks (87). Starting with the premise that a better predictor of LBP is precisely a positive medical history and the awareness that children and adolescents exhibit significant differences regarding medical history, physical examination, and diagnosis compared to the adult population (88), it would appear altogether appropriate that new studies be conducted so as to bring this subgroup to the fore and thereby formulate better treatment and avoid the relapse of LBP in adulthood.

### Diagnostic Therapeutic Flowcharts

Subsequent to the pioneering experience, not only for LBP but also for medicine in general, of the Quebec Task Force down in 1987 (89), which represented the first systematic effort to produce a CG in terms of a summary of the existing evidence on LBP treatment, this field has been one of the most prolific for CGs production (10,90). In this context, with the objective of painting in a simple way the everyday clinical behaviors, those published in 2006 in *Europa Medicophysica* (9) (now the *European Journal of Physical and Rehabilitation Medicine*) (91) appear very interesting. The “Diagnostic Therapeutic Flowcharts for LBP Patients” (DTP) have been developed as real flowcharts (Figs. 33-1, 33-2, 33-5, 33-7, 33-9, 33-11, and 33-13), in order to provide a complete idea of what should be done, and to cover, through expert multidisciplinary consensus, the multiple gray areas in which the actual evidence does not offer answers. Moreover, these DTP have other unique characteristics in terms of PRM (21) that are reported below. In Figures 33-2, 33-5, 33-7, 33-9, 33-11, and 33-13, the most

interesting flowcharts of the DTP are given to the reader, while in the open access version of the *European Journal of Physical and Rehabilitation Medicine* (EJPRM) ([www.ejprm.org](http://www.ejprm.org)) they can be viewed for further details.

The DTP have been developed through a systematic search of the literature and a multidisciplinary consensus of all Italian scientific societies engaged in this field. The classical distinction between ALBP, SALBP, and CLBP is at the base of the DTP. Even though a recurrent form of LBP was hypothesized at the start of the DTP project, the absence of literature and the lack of any evidence on the possibility of differentiating a recurrent episode from a single first episode of LBP made it necessary to eliminate this classification item (9).

One of the most interesting points is represented in the flowchart in Figure 33-2. In fact, while preparing the DTP it was discussed how to grade the importance of the different rehabilitation approaches possible for SALBP and CLBP patients. It was agreed that, from the viewpoint of rehabilitation and also prevention, the most important patients were the SALBP ones, where it was still possible to try avoiding chronization, which is the most awful end of the story, because it is extremely rare that a patient will exit from CLBP. In the meantime, which CLBP patient would deserve the highest attention so to reduce the burden of the biopsychosocial situation for them and for society? According to the literature, such a choice has been defined using the level of disability as a way to discriminate among patients (9,21). This is a totally new conceptual development, but it is consistent with the actual knowledge of CLBP (22). Moreover, the actual disease-specific disability questionnaires have already defined cut-off levels in order to distinguish high-disability and low-disability patients (48,81). This conceptual step forward provides a means by which to classify the various possible treatments (see Fig. 33-2).

Another important point of the DTP has been to recognize the importance not only of the therapy proposed but also

**FIGURE 33-1.** Overview of the flowcharts reported in the “Diagnostic Therapeutic Flowcharts for LBP Patients” published in 2006 in *Europa Medicophysica*, now the *European Journal of Physical and Rehabilitation Medicine*. The classification of LBP used can be easily gathered (9).

## Notes

1. Arthrosis: discopathy, osteophytosis, reduction of discal space, and/or vertebral endplates thickening. Usually these are radiological diagnosis without any relevance.
2. Neuro-muscular spinal instability (different from the osteo-ligamentous one) has not been defined in the literature. It's possible to consider the following criteria:
  - sharp and brief acute pain following sudden position changes and/or efforts
  - pain during stabilization tests: e.g. sudden release after isometric contraction of hip muscles (flexion, adduction, abduction), trunk destabilization
3. Scoliosis over 30° can progress in adulthood and needs specialistic control.
4. See Table 1.

FIGURE 33-2. Subacute and CLBP diagnostic flowchart (9).

the other elements constituting a complete approach to LBP patients. This starts with the biopsychosocial theory, which is the basis of a modern approach to LBP patients (3,4). It clearly contradicts the usual disease-oriented approach, where only therapy could be considered enough. This is correct and typical of CGs for specific diseases, but it is incorrectly maintained for analogy in the field of LBP. Consequently, in the DTP all therapeutic schemes (Tables 33-4 through 33-8), including those on secondary LBP, consider counseling, work and activities of daily living (ADL) interventions, physical activity counseling, PO therapy, and specific FO rehabilitation. Again it emphasizes the importance of all these elements in approaching what is not a “simple” disease but is instead a biopsychosocial syndrome.

Secondary LBP is usually not included in CGs (10), eventually with the exception of disk herniation (DH): In the DTP there are also specific flowcharts for spinal stenosis, spondilolisthesis and spinal instability, adult scoliosis (AS), spondiloarthritis. Excluding the last one, where a specific rheumatologic approach is proposed, in the others the main ideas were as follows:

- Identify specific cut-offs for the eventual proposal of surgery;
- A part from rare medical urgencies, postpone in any case surgery after an appropriate complete rehabilitation process;
- Verify the absence of contraindications to surgery;
- Fully inform the patient regarding the advantages and disadvantages so as to allow an individual, informed choice.

For each secondary LBP clinical picture, specific rehabilitation is listed according to the actual literature. For example, the best types of exercises are proposed even if there is no definitive proof in the literature today, but this is obviously discussed according to the strength of evidence.

The different flowcharts (modified) will be reported throughout this text when appropriate (see Figs. 33-2, 33-5, 33-7, 33-9, 33-11, and 33-13).

## Rehabilitation Approach: Treatment Tools

### Actual Evidence in the Literature

Many therapies are proposed in LBP management in everyday clinical practice. For some therapies there are no data at all or limited evidence at best. Occasionally, the only rationale of prescription is traditional, while for others we can rely on more consistent findings. We distinguish the treatment options as PO treatments (oral drugs and injections, physical therapies, manipulations), FO approaches, and educational interventions (9). This distinction could now appear to some readers less than totally justified: in fact, most of the PO approaches propose themselves as “normalizers” of physiology and/or “aetiological” (34,61,92–96), but to date there are no scientific proofs of these hypotheses. Moreover, according to the actual literature we will consider together ALBP and SALBP because there are not enough papers to make a real distinction between the two.

## Acute and Subacute LBP

### Pain Management

Nonsteroidal anti-inflammatory drugs (NSAIDs) have been shown to be more effective than placebo concerning a general effect on ALBP. However, no single NSAID molecule overcame the others in terms of effectiveness. There is moderate evidence that NSAIDs are not more effective than paracetamol for ALBP, and paracetamol had fewer side effects. Traditional NSAIDs seem to have more gastric side-effects compared to COX-2, but there are no differences in terms of efficacy. In any case, the effect ranges are small. Benzodiazepines, as well as central muscle relaxants other than benzodiazepines, were shown to be more effective than placebo on ALBP (97).

Manipulations were shown to be more effective than placebo on pain in the short-term (within 6 weeks) but were not more effective on function (98). There is moderate evidence that lumbar supports are not more effective than no intervention or training in preventing LBP, and there is conflicting evidence about whether they are effective as supplements to other preventive interventions. It remains unclear whether lumbar supports are more effective than no or other interventions for the treatment of LBP (99).

No relevant data are available concerning steroid injections, oral colchicine, acupuncture, electromyographic biofeedback, lumbar supports, massage, transcutaneous electrical nerve stimulation (TENS), traction, thermic-effect based therapies (ultrasound, ice, heat), insoles (there is strong evidence that insoles are not effective for the prevention of LBP) as LBP treatments (98,100–103). Some herbal medicines (*harpagophytum procumbens*, *salix alba*, and *capsicum frutescens*) seem to reduce pain more than placebo (104).

### Educational Interventions

Advice to stay active is effective and sufficient for the long-term improvement of function in ALBP (105,106). The indication to rest in bed is less effective than the indication to stay active (107). There is strong evidence that an individual 2.5-hour session of oral education is more effective on short- and long-term return-to-work than no intervention. Educational interventions that were less intensive were not more effective than no intervention (108). There are no randomized controlled trials (RCTs) on ALBP using back schools (109).

### Function-Oriented Rehabilitation Approaches

There are no RCTs on ALBP considering the multidisciplinary rehabilitation treatments. Exercises showed no effect in the first 2 weeks of LBP, but they were shown to be effective in SALBP in the occupational setting (110). There is some evidence that the McKenzie method is more effective than passive therapy for ALBP. However, the magnitude of the difference suggests the absence of clinically significant effects (63).

## Chronic LBP

### *Function-Oriented Rehabilitation Approaches*

Strong evidence exists to the effect that intensive multidisciplinary biopsychosocial rehabilitation with a functional restoration approach improves function as compared to inpatient or outpatient non-multidisciplinary treatments. There is reasonable evidence that this approach improves pain as compared to outpatient non-multidisciplinary rehabilitation or usual care. There is contradictory evidence regarding vocational outcomes of intensive multidisciplinary biopsychosocial intervention (42).

Combined respondent-cognitive therapy and progressive relaxation therapy are more effective than waiting-list controls on short-term pain relief. However, it is unknown whether these results can be sustained in the long term. No significant difference has been detected between behavioral treatment and exercise therapy (111). A short-period of cognitive behavioral treatment and exercise therapy has a modest effect on pain and disability at one year. This effect can be influenced by preference toward treatment (112).

Exercise therapy appears to be slightly effective at decreasing pain and improving function in adults with CLBP, particularly in health care populations (110). There is limited evidence regarding the use of McKenzie method in CLBP. The effectiveness of classification-based McKenzie is yet to be established (63).

### *Educational Interventions*

The effectiveness of individual education is still unclear (108). However, there is moderate evidence suggesting that back schools, in an occupational setting, reduce pain and improve function and return-to-work status in the short term and intermediate term as compared to exercises, manipulation, myofascial therapy, advice, placebo, or waiting-list controls for patients with chronic and recurrent LBP (109).

Regarding CLBP, there is strong evidence to support the use of advice to remain active, in addition to specific advice relating to the most appropriate exercise and/or functional activities by which to promote active self-management (106).

### *Pain Management*

No clear evidence exists to the effect that antidepressants are more effective than placebo in the management of patients with CLBP. These findings do not imply that severely depressed patients with LBP should not be treated with antidepressants (113). The benefits of opioids in clinical practice for the long-term management of CLBP remain questionable (114).

Both TENS and traction, as a single treatment for LBP, are probably not effective (101,115). Low-level laser therapy (LLLT), in contrast to a sham treatment, may be beneficial for pain relief and improved disability in patients with SALBP or CLBP, although the treatment effects are small. However, when LLLT is added to exercise and compared to exercise therapy, either with or without sham treatments, there appears to be little or no difference between the groups in terms of pain and disability (116).

The evidence is conflictive in regard to the efficacy of prolotherapy injections for patients with CLBP. When used alone, prolotherapy is not an effective treatment for CLBP, but combined with spinal manipulation, exercise, and other interventions it may improve CLBP and decrease disability (117).

### *Rehabilitation Tools*

The rehabilitation treatment tools used in the field of LBP have three different backgrounds: mainly physical (exercises); mainly psychological (cognitive-behavioral approaches); finally social (education approaches). These are only tools that can be combined in a thorough rehabilitation of the individual patient so as to achieve the best results. They should not be considered separately, but only as ingredients in the correct mix designed to achieve the best individual rehabilitation. In fact, there is strong evidence that intensive multidisciplinary biopsychosocial rehabilitation with a functional restoration approach is useful for CLBP (41,42): in this case, the complete rehab package includes exercises (functional restoration) (118,119) together with psychological (cognitive-behavioral) (111) and social approaches to the patient (40,42) that allows to achieve the best results.

### *Exercises*

The use of exercises as a therapeutic tool for LBP is quite common in most countries of the West (120), despite scientific evidence that shows its efficacy to be quite inconsistent. In a 2000 Cochrane review, the authors highlight the modest effectiveness of exercises in treatment for patients with CLBP while noting its effectiveness in reducing work absenteeism in patients with SALBP. In ALBP, the benefits of exercises are considered to be as effective as conservative treatment or non-treatment (110).

The low effectiveness of exercises, as reported in a great number of studies published in scientific journals, is in contrast to the benefits perceived by patients and experts in the treatment of LBP. This discrepancy may be due to the fact that in a great number of these studies with high scientific impact the subjects are randomly chosen and placed in various treatment groups without being first classified into subgroups based on the criteria of pain characteristics (121–124). Such a method, being conceptually flawed from the outset, can skew the outcome of clinical trial results. Because classification based on a proposed relevant pathology is possible in at least 10% of cases (125), one of the objectives of a diagnostic procedure would be to allow the collection of data useful in placing subjects in homogeneous groups in order to prescribe the most appropriate treatment (121). If it is not possible to classify according to etiology, presumably it will be possible for functional characteristics, or others that are now under scientific exploration. Until then, we have to wait before being able to state clearly what the evidence on exercises can be.

Moreover, this may explain why various types of exercise—albeit with very different physiological origins—have all shown benefits in treating LBP, particularly CLBP (110,120,126).

A few years ago, an open question in the treatment of patients with LBP was to explore whether trunk-flexion exercises would be more efficient than trunk-extension exercises. Studies did not completely resolve this question because the choice of prescribing a preferred course of exercises could not be entrusted to randomness but instead through a careful examination of subjects based on the characteristics of the symptom and its modification (62). Recently, an in-depth meta-analytical study examined precisely the types of exercises that were potentially the most effective in the treatment of CLBP (110,120,126). While promising results emerged from the study, both in the area of muscle stretching and strengthening, its main conclusion was that much more research would be needed before a better definition of protocols could be reached, and that the best course is most likely that of subclassifying patients.

The objectives of exercise (Fig. 33-3) could include:

- Reducing symptoms;
- Regaining function, reducing disability and fears related to movement, and encouraging regular physical activity in SALBP and/or CLBP;
- Preventing relapse.

Reducing the sensation of pain could be linked to biological changes in tissues, thanks to increased blood circulation, improved mechanics of the joints in question due to the stimulation of joint capsules and their ligaments, better function of stabilizer muscles, and a neurological de-sensitization of tissues, thanks to the repetition of movement (127).

In SALBP and CLBP, along with pain the patient must also face various other problems. Many studies have shown that “pain-related fear” has a negative impact on some basic spinal functions, such as elasticity and strength (128). This condition increases the risk of a progressive worsening of disability and the development of a deconditioning syndrome, which could be an additional obstacle to improving conditions. Another typical behavior is that a CLBP patient may exhibit “avoidance behavior”: The patient fears incurring back damage and adopts motor behavior marked by excessive caution (129), which further worsens motor neurological quality. An intensive, targeted exercise program could reduce the risk of kinesiophobia and have a positive impact on the related disability (130,131). In this respect, there are proofs that a graded increased functional training has good results in SALBP (132–134), but this methodology can quite easily be extended to CLBP patients (110,120) allowing to achieve cognitive-behavioral goals as well (111).

There are many studies that have shown how the characteristics of the muscles that maintain the stability of the spine change after an episode of LBP. The lumbar multifidus muscle exhibits a delayed activation (135) and a decrease in the transversal size on the side of the pain (136). It has been observed notably that in the absence of specific treatment these deficits remain, even when the LBP disappears. The high incidence of recurrence in LBP the year after the first episode could be due to precisely this functional weakness in the stabilizer muscles. Some studies have supported this hypothesis by showing how

**FIGURE 33-3.** Examples of exercises that can be performed by patients with LBP with different aims. **A:** Development of kinesiophobia is one of the main elements to avoid in CLBP management: for this reason patient must experiment kind of movement as far as complex. **B:** Trunk and pelvis imbalancing exercise to improve coordination and motor control of the spine.

a program of functional reactivation of these muscles could work as a safeguard against future episodes. A year after an episode, a group of subjects who had participated in a specific program for strengthening the lumbar multifidus muscle had a 30% rate of relapse compared to 84% in the group of patients who had not participated. Even a follow-up three years later revealed a significant difference in the results, with a 35% rate of relapse in the group tested compared to 75% in the control group (137).

The same results were observed for adolescent LBP (138,139). The choice of favoring a program of stabilizing exercises to prevent the relapse of LBP is not clearly supported by scientific literature. In the case of recurrent nonspecific LBP, a program of general exercise reduces disability more effectively than a program centered on stabilizing the spine, which should only be an option for cases having obvious signs of instability.

Finally, the so-called functional rehabilitation approach is discussed (41,118,140,141). This gained popularity in the recent past and has been proposed as an inpatient intensive training of 3 to 5 weeks (142,143) or as a long-term training program, mainly machine-guided outpatient training (67,119,144). The main theory at the basis of this approach is derived from sports medicine (141) and considers function more than pain: in fact results are best in the functional-disability domains than on the pain itself that is in any case decreased (41). Even without considering that any kind of rehabilitation by definition must be “functional” (22), this approach has shown good results (41) and must be adopted as a concept, even if other settings (i.e., outpatient without specific machines) can be considered apart from the ones presented in the literature.

### Cognitive Behavioral Approach

Cognitive-behavioral intervention is commonly used in the treatment of disabling CLBP, and it originates from a new viewpoint in regard to chronic pain. The traditional medical approach considers pain as a cause of illness and consequent disability according to an established illness model (4,12). This provides a circle in which physical damage causes pain that will eventually cause impairment, and the impairment will ultimately induce a disability. Nevertheless, while acute pain has a biologic means of alarm to signal tissue damage, chronic pain lacks this characteristic; it is not only influenced by somatic pathology but also by psychological and social factors (44). Moving from this consideration, Waddell (Fig. 33-4) theorized a new model of illness for LBP, known as biopsychosocial model, in which various aspects can determine and explain chronic pain. They are:

- **Physical dysfunction:** It depends on an imbalance between the demands of physical ability and real body capacities that are not ready to provide the required performances.
- **Belief and coping:** Human thought and the way of perceiving pain play a crucial role in determining how the patient manages his health problem. Frequently, patients with CLBP are persuaded that they suffer from a serious pathology and are therefore hardly considered curable. They have incorrect assumptions about the possibility of recovery, often due to previous failed treatment. This leads them to adopt a discouraged approach to the problem and to new proposed treatments. The different strategy for coping with pain can explain why certain patients overcome the acute phase, while others come to suffer from CLBP. There are two means of response to pain: actively face it (copers), or

**FIGURE 33-4.** The biopsychosocial model of illness for LBP as proposed by Waddell (4): various aspects can determine and explain chronic pain.

undergo it (noncopers). Pain-related fear, catastrophizing beliefs, and lack of psychological and cognitive instruments with which to oppose painful symptoms lead the patient to assume an avoidance behavior from the same pain. This means the reduction of physical activity, work, and social relationships until one arrives at a physical and psychological deconditioning.

- **Distress:** Increased pain perception, emotional stimulus, psychological factors are deeply linked, and they can give rise to a vicious circle. Feelings of fear, anxiety, anger, and depression are common in patients of this kind.
- **Illness behavior:** It is heavily conditioned from prejudices about the pathology, future treatments, and the ability of medical care to resolve the pain.
- **Social relationship:** Social networks such as family, friends, and colleagues can influence the emotional status, development of illness beliefs, and coping strategy. A favorable family activity can help to face and overcome pain, while an accommodating ground to illness will increase it. This model provides a multidisciplinary approach to the problem that requires, above all, a multidisciplinary treatment through the use of different techniques appropriate for the individual subject, such as his or her psychological state.

Two systematic Cochrane reviews (42,111) and additional trials (132,133,145), all of which are considered high quality studies, showed there is strong evidence that behavioral treatment is more effective for pain, functional status, and behavioral outcomes than placebo, no treatment, and waiting-list control, most of all when it is intensive, and that a graded activity program using a behavioral approach is more effective

than traditional care for returning to work. One low-quality trial (146) found there is no difference between the effects of behavioral therapy and exercise therapy in terms of pain, functional status, or depression for as long as a year after treatment.

The goal of the cognitive-behavioral approach to nonspecific CLBP is the ability to modify wrong beliefs about health status and changing the perception of health. Weisenberg (147) and Meichenbaum (148), who in 1977 first introduced this model, support the importance of change in the health pattern by a cognitive incentive, seeking to modify the patient's relationship with the chronic pain by offering him/her the possibility of reacting to pain through an awareness of the real problem. This approach must be presented to the patient like a process of correct learning (14,30), in the passage from an illness behavior to a wellness behavior. Generally, three behavioral treatment approaches can be distinguished (149,150):

- Operant treatment, which is based on the operant conditioning principles of Skinner (151) and applied to pain by Fordyce (152) consists of the positive reinforcement of healthy behaviors;
- Cognitive treatment, which aims to identify and modify the patient's cognitions regarding his/her pain and disability;
- Respondent treatment, which aims to modify the physiological response system directly.

The first therapeutic aim is to forecast the positive effects of treatment results by acting on external events. This approach allows the patient to move from a control pain model, typical of the acute phase while improving behavioral and functional ability through communication, education, and motivation, which are methodological instruments peculiar to the cognitive-behavioral model. Communication must be efficacious and bidirectional in order to educate the patient in viewing his health condition from the correct perspective. Physicians and therapists should ensure that the patient understands his/her problem and that they are ready to help. Only in this way they can gain the patient's confidence, which is necessary to ensure good compliance with the treatment. The advantage of the educational program is to offer the patient explanations about the true extent of the problem through easy lessons about anatomy and physiology until the patient can be clearly informed in regard to CLBP. It is useful to encourage the patient to manage his/her pain instead of simply suffering, and giving him/her simple means to be applied in his/her everyday life. This is done by explaining how this active approach to LBP influences, in a crucial way, the perception of pain and the disability correlated to it. This does not signify the minimization of the problem, but instead it helps the patient face it, rid himself from incorrect beliefs and the behaviors of pain avoidance that only serve to strengthen the pain.

The methodology applied is not simply "learn to change" but also "test the change." To follow this model it is necessary to establish, before treatment begins, certain realistic aims, and to document the improvements through self-evaluation

techniques for involving the patient so that he/she will be responsible for the change. The operating setup of this theoretical warning is to test during daily living what the patient learns and to make him/her aware of improvements. Central to diagnostic evaluation is an understanding of the deep interactions between the physical and psychosocial factors, and how they can support themselves according to a vicious circle, since disability in this kind of patient also means chronic pain, physical dysfunction, and illness behavior.

### Educational Tools

A primary objective of LBP management is to provide the patient with accurate information. LBP treatment strategies have changed through the past few decades, thanks to the results of various clinical trials conducted during this period. An emblematic example of this is the general consensus regarding the recommendation of remaining active as much as possible during cases of ALBP (153). However, while it is an important element of LBP primary care, this consensus is not a widely held belief and many people continue to believe their patients need rest.

Accordingly, an updated collection of data to adequately address the issue is an important tool in modifying popular beliefs. In the case of ALBP, it is crucial to reassure the patient and inform him or her of the appropriate methods for managing symptoms (106). In the case of SALBP, the information must be particularly targeted toward the prevention of chronicity by providing the patient with useful advice on how to identify any behavior that could delay healing (106). As for CLBP, the information should include advice on how to manage pain, control catastrophism, and decrease avoidance behavior (106,111).

Certainly, an informational brochure is the most common educational tool (154,155). Many experiments have been carried out to quantify the brochure's tangible effectiveness in changing common perceptions among patients, modifying behavior, and having an impact on pain and disability. For ALBP patients, the information contained in a brochure seems to be quite effective in reducing pain and the likelihood of relapse (156), as well as in decreasing fear-avoidance behavior (154). The brochure has also been used among the institutionalized elderly, and has shown a positive impact on improving disability in the 6 months following its use (157).

Back schools have been proposed in the past as a possible important tool for LBP treatment (106,109), and for a period of time they were quite popular. However, they have been widely criticized (158) because the original proposals (159–162) were mainly based on ergonomic assumptions and a disease-oriented model of illness that was clearly overcome by the actual biopsychosocial one. Nevertheless, the back school can be considered a therapeutic tool that can be filled with the most actual contents and/or according to the individual needs and/or clinical realities, more than a schematically uniform treatment. In everyday clinics this is the reality, because there are as many back schools as there are therapists applying them. Today there are some proofs of

efficacy, mainly in specific professional settings (109). As a therapeutic tool, if it is used as a cognitive behavioral exercise-based group approach to nonspecific SALBP and/or CLBP, the back school can be important as a low-cost approach to large numbers of patients (9).

Media is another interesting information tool for educational purposes. With a multimedia information campaign, a significant change can be observed in popular beliefs, with a considerable number of people abandoning the notion that they need rest when experiencing pain and instead embracing the correct idea of remaining active (163). This change in behavior is cost-effective and continues for several years after the end of the information campaign (25).

Lastly, various studies have shown that a crucial element in reducing the cost of LBP primary care management is the awareness of getting family physicians to adopt the right behavior (164), in which a multimedia campaign could play a part.

### Main Pain Management Tools of PRM Interest

These approaches have different backgrounds, according to the pathoanatomic hypotheses proposed by the different authors and schools who have developed or use each of the tools. Some have a certain efficacy, but not in all patients: In an evidence-based clinical practice view they should be regarded not for their theory but only for their efficacy. Moreover, to date there is no consensus on how to choose each single treatment for each single patient (9). Presumably, and as far as we know today, the best way is through trial and error, starting with what is preferred by the patient and the treating physician. What should be avoided is absolute approach, coming from the idea of superiority of the PO treatment proposed versus any other, and based on specific diagnoses (diagnostic labels) (165,166) not scientifically sound: in fact it has been shown that such a medical style highly increases the probability of chronicization (96,165,167), constituting an important, iatrogenic yellow flag.

### Manual Approaches

Hands are probably the most ancient tool man has employed in bringing relief for LBP. Both written evidence and artistic representations show that manual methods were highly valued even when very simple techniques were used, because there was little knowledge of anatomy and the mechanisms of joint physiology. Over the centuries, the progress of knowledge and wider experience have led to the development of various manual techniques for the treatment of LBP.

The term “manual therapy” includes techniques aimed primarily at the treatment of soft tissues, such as massage, mobilization techniques carried out to increase the range of motion, and techniques based on the application of small-amplitude high-velocity thrusts, such as manipulation (168). Theories proposed on the way of action of manual therapies are almost as many as the different schools (34); terminologies such as “osteopathic lesion,” “minor vertebral derangement,” all supposing little injuries of the mobile segment mainly at the

zygapophyseal joints, have been proposed; nonetheless, until any of these possible lesions will be proved this treatment is definitely a PO one.

Massage is undoubtedly the most ancient and widely used form of manual therapy. It is practiced in every region of the world and through a variety of techniques. Massage has also spurred considerable scientific interest, and this is shown in the large number of systematic reviews conducted by Cochrane to explore the effectiveness of its use. The results of these reviews on massage and LBP (169) have led to the conclusion that massage is effective in SALBP and CLBP, particularly when combined with exercise and education. The authors recommend further studies that would corroborate these conclusions and properly assess the cost-benefit ratio of manual therapy, its long-term impact, and the resumption of work.

Osteopathy and manipulation are two other manual therapy techniques widely used to fight LBP. While there is not much literature on the benefits of the former for treating LBP, there is considerably more in regard to the latter. One such review by Cochrane shows that in the treatment for ALBP and CLBP, manipulations are only more effective than sham therapies. There is no evidence that they are more beneficial than traditional treatments such as exercise or painkillers (170). Considering the low benefits and high cost, the effectiveness of these treatments is also low. However, it should be noted that when therapeutic techniques are characterized by a close relationship between the patient and the therapist—as in the case of manual therapy—even in those cases of treatment failure only 50% of the patients require alternative therapies, most likely because the ties forged with the therapist enable the patient to better face the symptoms and disability (171).

### Modalities of Physical Therapy

Modalities of physical therapy include a wide variety of devices that apply physical principles in treating many problems in rehabilitative medicine. Actually, it is frequently proposed in LBP management in everyday clinical practice, sometimes alone but sometimes as part of a more complex approach. Despite the specific principle behind the action of each device, it can be considered a PO therapy because they act mainly on pain perception and transmission, even if they are supposed to possibly act on cell membrane or on inflammation.

Electricity is probably the main physical principle applied in this field, and within this group TENS is probably the form most commonly used. The development and application of TENS was based on the Gate Control Theory conceptualized by Melzack and Wall (172). According to this theory, the stimulation of large-diameter (A- $\beta$ ) primary sensory afferents activates inhibitory interneurons in the substantia gelatinosa of the spinal cord dorsal horn, thereby accentuating the transmission of nociceptive signals from small-diameter A- $\delta$  and C-fibers (172,173). Supraspinal mechanisms involving the endogenous opioid system have also been described (174–177). In summary, the postulated effect of TENS is to “close the gate” and dampen the perception of pain (172). Despite its rationale and well-documented biological effects, TENS as

a single treatment for LBP is probably ineffective (101,115). Other forms of electrical therapy have been proposed, and some papers have been published (178,179), even if we still lack a substantial basis for them.

Ultrasound has for many years been used in the treatment of musculoskeletal conditions. Laboratory research has demonstrated the application of ultrasound results in the promotion of cellular metabolic rate and increased viscoelastic properties of collagen (180). In animal studies, an exposure to 1 MHz ultrasound at 50 J/cm<sup>2</sup> is reported to be sufficient for the increase of tissue temperature (181). This rise in temperature is assumed to be the mediating mechanism for tissue repair, enhancement of soft-tissue extensibility, promotion of muscle relaxation, augmentation of blood flow, and alleviation of inflammatory reactions of soft tissue (180,182–184). Despite the theoretical benefits and widespread use, conclusive evidence on the effectiveness of ultrasound therapy in CLBP is not yet available.

LLLT is currently used by some as a therapeutic intervention for musculoskeletal disorders such as LBP (185,186). LLLT is a light-source treatment that generates light of a specific wavelength. It emits no heat, sound, or vibration. Instead of producing a thermal effect, LLLT may act through nonthermal or photochemical reactions in cells. It is also referred to as photobiology or biostimulation (187,188). LLLT is thought to affect fibroblast function and accelerate the repair of connective tissue (189). It has also been reported that LLLT has anti-inflammatory effects due to its action in reducing prostaglandin synthesis (190). Some studies suggest that LLLT has a beneficial anti-inflammatory and pain-attenuation effect in humans (191). A possible mechanism of the effect of LLLT on pain relief is its anti-inflammatory and connective-tissue repair process, which have been shown in some *in-vitro* and *in-vivo* studies (190,192). The effectiveness of laser therapy in painful disorders is still unclear and should therefore be examined more rigorously (185,193).

Pulsed magnetic field therapy (PMFT) is a simple, noninvasive technique used extensively for the treatment of muscle pain (194). This technique is based on changes in the cell membrane induced by magnetic fields (MF) and, to a limited extent, the electric field. Exposure to pulsed MF has been shown to have a therapeutic benefit in both animals and humans. MF exposure does not affect basic human perception but can increase pain thresholds in a manner indicative of an analgesic response (194). Nevertheless, no data is available regarding the effect of MF on CLBP.

All the aforementioned physical therapies have some basic research studies and have been widely applied, but conclusive research on their efficacy is lacking. These approaches can be considered in the PO phase of an integrated rehabilitative process, but until there is further proof they should be avoided as stand-alone LBP treatments.

## Drugs

Pharmacological treatment is the first way to control pain in patients with LBP. There are various kinds of medications, and each one has a unique balance of risks and benefits. A systematic

Cochrane review (97) of NSAIDs—which are widely used in LBP—demonstrated that there is a moderate evidence that NSAIDs are not more effective than other drugs for ALBP, and there is a strong evidence that various type of NSAIDs (including COX-2 NSAIDs) are equally effective. COX-2 NSAIDs had statistically significantly fewer side-effects than traditional NSAIDs, but recent studies have shown that COX-2 inhibitors are associated with increased cardiovascular risk in specific patient populations.

The use of muscle relaxants (195) in the management of nonspecific LBP is controversial even if they seem to be effective. However, the adverse effects—particularly, the effects on the central nervous system—require caution in the use of muscle relaxants. The potential for tolerance and withdrawal, combined with the risk of misuse and dependency, lead clinicians to restrict the prescription of opioids, even if they are commonly used for CLBP and may be efficacious for short-term pain relief. The long-term efficacy (>16 weeks) is unclear (114,196). A Cochrane review (113) reported that there is no clear evidence that antidepressants are more effective than placebo, even if such findings do not imply that severely depressed patients with LBP should not be treated with antidepressants.

A pharmacological strategy for the treatment of LBP, particularly in regard to leg pain, is the epidural injection of corticosteroids, for which (92) there does not appear to be any evidence to support the current common practice of a series of injections. Abdi et al. (197) reported that there is limited evidence regarding the lumbar spine for long-term relief for interlaminar epidurals and moderate long-term improvement in managing nerve-root pain for transforaminal epidural steroid injection.

A review of evidence for an American Pain Society/American College of Physicians (198) recently summarized this knowledge in terms of good short-term evidence with moderate effectiveness for NSAIDs, acetaminophen, and skeletal muscle relaxant (for ALBP), while the minimal one proposed on tricyclic antidepressant for CLBP has been overcome, according to the last Cochrane review (113). They also found a reasonable amount of evidence that opioids, tramadol, benzodiazepines, and gabapentin (for radiculopathy) are effective for pain relief as opposed to systemic corticosteroids, which the evidence strongly suggested was ineffective. The authors found that evidence is insufficient to identify one medication as offering a clear overall net advantage due to the complex tradeoffs between benefits and objectives. This leads to the choice of one or more medications after a specific analysis for each patient, taking into account the comorbidity and others drugs just assumed.

## Low Back Pain

We definitively recognize, according to the actual knowledge, the term “LBP” as a diagnosis instead of being merely a symptom. LBP diagnosis is made by exclusion through a triage (5): in such cases other terms such as “sprain,” “injury,” “trouble,” or “lumbago” have been used for years, in most cases supposing and supporting the idea of different specific patho-anatomic background. Today the scientific community has abandoned this approach: the most up-to-date classification

of LBP is based on the localization and on the duration of pain (3,8–10). Even if this could appear as an epidemiologic framework unduly applied to the clinical field, actually it is the only real way to differentiate patients with different prognoses and pathologies. Hopefully in the future it will be possible to deepen this broad classification, but it is already a good way to arrive at clinical and rehabilitative everyday choices.

Research thus continues its gradual progress toward the subclassification of different syndromes, mainly with the objective of increasing the quality of approach (62,122,124). However, this process will take years to reach a satisfactory conclusion.

The incidence, prevalence, and costs of LBP are incredibly high (59,199–205). ALBP life prevalence is more than 80% of the population, year prevalence counts up to 30%, and costs in terms of absenteeism rank second in importance, following only cold and flu. However, over 90% of ALBP resolve in less than 30 days; on the other side, CLBP is an everyday experience for 4% to 7% of the population. It consumes 75% to 80% of the entire enormous costs of LBP and less than 5% of patients achieve a complete resolution of pain. SALBP has scarcely been studied and today we have no reliable epidemiological data, even if this stage of pathology should deserve the highest attention.

## Acute LBP

### Definition and Pathogenesis

ALBP is defined as pain or discomfort in the lumbar region, on one or both sides, eventually irradiating to the buttocks and lasting no more than a month (3,8,9,52). What really characterizes ALBP is that we do not know exactly where it comes from (96,165): Presumably, we can exclude the involvement of bones and main nerves. Instead, soft tissues are the main actors (muscles, ligaments, apophyseal joints), together with discs eventually and/or vessels, and/or the sympathetic nervous system. Nevertheless, the hypotheses are as numerous as the authors who have studied them.

### Clinical Presentation

ALBP is clinically multiform: it can appear suddenly when one encounters a significant physical effort, or it can appear without an apparent cause. It can start insidiously, or it can arrive at the complete lumbar blockage. It can start on one side and move to the other, or remain fixed in time. Independently from the quantity of pain, it can last from several minutes to several weeks. Apparently the level of pain has no correlation with the anatomical lesion and its recovery.

### Diagnosis, Classification, and Prognosis

Diagnosis is made by exclusion, and it must be done only through clinical examination (3,8,9,52). Red flags must be carefully excluded (see Table 33-1), and if there are no warning signs the health risk and the costs of imaging, and other exams will not be justified (3,8,9,52). Today we have no useful accepted subclassification, even if scientific efforts are underway

in this respect (121,123). Prognosis is very good: ALBP is auto-resolving in most of the cases, usually in less than a month (59,206). Most of the time, ALBP is recurrent (206–208). Even if there is a clinical widespread suspicion, there is no proof that it implies a progressive worsening of the clinical situation (9).

### Treatment Approaches

ALBP should be treated mainly by general practitioners (GPs), both to reduce costs and increase clinical long-term results (9,23,25,209–211). The main objective and therapy in ALBP is, in fact, to reassure the patient and provide accurate preventive information (3,8,9,52). PO treatment is useful but secondary, even in the eyes of patients (212). Specialists should reinforce the role of the GPs and eventually offer them an educational support (23,210).

### Rehabilitation Approach

There are very few issues on which the international scientific community has reached a general consensus. One of these issues is the right behavior to adopt in cases of ALBP. The key recommendation is to remain as active as possible and to avoid bed rest. This advice stems from consistent results (207,213) from a large number of scientific studies that have prompted the publication of a Cochrane review (169) whose findings recommend not to invest any further effort in examining this issue, as it has been abundantly proven.

With regard to LBP, the term “rehabilitation approach” is a bit of a misnomer, as a patient suffering from LBP for less than a month does not present any disability at this stage, and education appears far more appropriate. This patient merely needs reassurance and support until symptoms disappear.

Caring for a patient suffering from ALBP should, however, take into account two important factors related to prevention simultaneously: avoiding chronicity and regaining any fitness lost during the period of acute pain which may open the way to frequent relapses.

The real issue with LBP entails the progression from an isolated episode into chronic pain. This transformation depends on a complex series of not always identifiable psychosocial factors, “yellow flags” (58,59,214) that must be carefully taken into consideration and which could enable the health care provider to distinguish between a single episode of LBP and the transformation into a chronic disorder (215).

Many studies reveal how LBP brings about a rapid change in the function of the paravertebral and stabilizer muscles (136,216,217). It was noted, in particular, how rehabilitation of the musculature is not spontaneous with the disappearance of the symptoms and it is believed that this deficit may be one of the reasons for the frequent relapses reported after an episode of LBP (137). Studies have shown that the rate of relapse drops drastically when the patient participates in a rehabilitation program focused specifically on the stabilizer muscles. A short-term follow-up (1 year) shows that the relapse rate drops from 87% in the group that did not participate in a specific program to 30% in the group that did follow the program. This same gap also holds for

the medium term. The probability of experiencing LBP 3 years following the first episode is 35% in subjects who participated in a specific exercise program, compared to 75% in subjects who returned to their daily routine without exercise (137,218).

### Subacute LBP

This is the less known type of LBP, and research in this field is really lacking, even if in recent years it has progressively flourished due to the understanding of the key role of this stage of LBP.

### Definition and Pathogenesis

SALBP is defined as pain or discomfort in the lumbar region, on one or both sides, eventually irradiating to the buttocks and lasting more than 1 month but less than 6 months (3,8,9,52). Some authors distinguish a subacute phase (1 to 3 months) and a subchronic phase (4 to 6 months), but there is neither epidemiological proof nor a real clinical decision based on that distinction. The pathogenesis of SALBP is complex. As far as we know, it is a real intermediate stage, being the passage between ALBP and CLBP. In this period, apparently there is something that impedes the spontaneous resolution of ALBP, maintains the previous situation, makes it more complex and gradually drives the patient, through a series of vicious cycles, to CLBP (4,12,219). These factors have been studied in these years and therefore recognized as the chronicization risk factors (see Table 33-1) (58,77,214,220–224). According to the definition of biopsychosocial syndrome, they can be divided into biological, psychological, and social factors. Moreover, certain other distinctions, as shown in the table, can be made. What can be supposed, according to the actual knowledge, is that an organic and definite cause of pain, which is manifested in the acute phase, cannot reach a resolution because of pre-existing factors and/or newly developed that appears in predisposed personal/social contextual factors. In this way the resolution becomes more difficult. The patient usually starts a pilgrimage between different specialists and professionals, each one giving his/her own etiological opinion, proposing a treatment, and using his/her own diagnostic labels (165,166). All this makes the situation progressively worse because it encourages the patient's feeling of having a bad pathology that is impossible to understand and cannot be treated in a definitive way.

### Clinical Presentation

Apparently, the SALBP patient is not very different from the ALBP patient, even if a careful history-taking and a good clinical examination can usually let the expert physician discover the stigmata of chronicization. A key factor is to look for the time passed since the inception of LBP, and another one is to let the patient speak freely about his or her problem. This way, if there are psychological and/or social disturbances, they usually come out quite easily, and the presence of relatives and their interrelations can offer other clues. What must be clearly pointed out is that these patients are usually quite the same on the surface, but with due time and careful evaluation it is possible to slowly

discover a multiform, individual manifestation of SALBP. Ultimately, this constitutes the real clinical presentation.

### Diagnosis, Classification, and Prognosis

Diagnosis, as is the case in all LBP situations, is made by exclusion. Nevertheless, it is widely recognized that further evaluation is needed at this stage, because true spinal pathologies must be excluded (3,8,9,52). Standing (and eventually dynamic) x-rays in the case of LBP, or MRI (and/or TC) in the case of sciatica, and eventually other ematological and/or neurophysiological exams according to each individual evaluation can be proposed (Figs. 33-2 and 33-5) (3,8,9,51,52). Nevertheless, these examinations should not be repeated continuously once the supposed pathology has been ruled out (51,225). As soon as a definite disease can be excluded, the patient should be evaluated carefully in a biopsychosocial way so as to understand which contributing factors are maintaining the pain, so that the patient can be treated accordingly. There are no subclassifications for these patients, nor is the prognosis as good as one might expect, even if treatment has a key role in this process (220).

### Treatment Approaches

SALBP is mainly of PRM interest (Table 33-4) (9,21). In fact, it is the situation in which it is still possible to avoid CLBP. However, this necessitates a definite rehabilitative approach. In this situation, maintaining a PO attitude that is usual in the disease-oriented specialties and in some “interventional” approaches, without being able to solve the problem definitively but instead using diagnostic labels, is a recognized risk factor of chronicization and should be avoided. Only a true biopsychosocial approach can lead to a possible resolution.

### Rehabilitation Approach

The approach to the SALBP patient is not easy because of the already painted multiform characteristics of these patients. Moreover, there is clearly a lack of research and the evidence is quite weak for all types of treatments (226). Nevertheless, a clear-cut clinical behavior emerges from research and the knowledge we have regarding ALBP and CLBP (see Table 33-4).

The first choice is to decide whether there is a need for PO treatment. There is evidence regarding its efficacy (226), even if drugs do not significantly decrease the disability (227), but this solution should be considered carefully because most often it is what the patient has always received, which usually means short-term results with no final resolution. Some patients will consider it a nonsolution, while others already run the risk of finishing in the “Saint Graal” vicious cycle (the infinite but sometimes impossible research for the “final solution” of their pain, possibly passive and without any individual effort), that physician behaviors can start and maintain. Consequently, a PO treatment can be proposed but should avoid any diagnostic label. Instead one should carefully explain that this is not the final solution but a treatment with possible short-term benefits that can be added to the compulsory FO rehabilitation.

Notes

1. Leg pain while walking always the same distance that disappears with flexion of the spine.
2. CT-scan is second choice screening exam.
3. Reduced strength, sensibility or reflexes with a metameric distribution and/or crossed SLR.

**FIGURE 33-5.** Subacute sciatica diagnostic flowchart (9).

Rehabilitation is the most important approach, combining educational, cognitive-behavioral, and physical exercise treatments according to the individual needs (40,228–231). Generally, patients in the first subacute stage are more in need of educational approaches than individual cognitive-behavioral ones, while the opposite appears more appropriate in later stages (subchronic ones), where the painful situation can be more established with many psychological and social vicious cycles already in effect (9). Nevertheless, these choices must be totally individual, as it happens for the physical-exercise approach whereby the evaluation leads to the exercise.

The approach to SALBP must definitely comprise a team. This is because a multiprofessional contribution facilitates a better understanding of the different risk factors involved, while maintaining coherent messages from different professionals has a crucial reinforcement role that allows the best results to be obtained. The multiprofessional evaluation must focus on the different risk factors of chronicity (see Table 33-1), so as to individually face these factors and prevent the establishment of the CLBP syndrome. Consequently, the physical, psychological, and social approach will change on an individual basis. This gives SALBP treatment the considerable adaptability required by the situation itself.

The efficacy of a psychological approach (232) to SALBP, even in the hands of specialists other than psychologists, has clearly been shown. Moreover, this is the only way to treat these patients who perceive themselves as “not mad” but as psychologically healthy. The psychological approach must be part of the treatment. However, it should be in the background instead of being the main goal, because most often the patient will not accept a direct psychological intervention and/or a treatment that is totally psychological. This is particularly so in SALBP, when the psychological implication of pain has not yet been fully understood by the patient and his or her relatives.

### Chronic LBP

#### Definition and Pathogenesis

CLBP is a pain with or without functional limitation in the posterior region, including the area between the inferior limit of the costal arch and the inferior buttock fold that lasts more than 6 months. Chronic sciatica is a pain in one or both legs that lasts more than 6 months. Given the absence of real differences between the two symptom presentations in terms of pathogenesis and clinical approach, they can be considered together (9). Even if the only difference between acute and chronic pain definitions seems to be the persistence of pain, their pathogeneses and clinical pictures are quite different.

**TABLE 33.4 SALBP Treatment (9)**

Evidence	Contents
	<b>Aim of Treatment</b>
A*	Patient at high risk of chronicity. Main aim of treatment is early, specific intervention on biopsychosocial risk factors of chronicity
A*	Symptomatic therapy could be useful, but multidisciplinary psychosocial intervention is necessary to avoid chronicization
A	<b>Counseling</b>
	Recovery can be slow
	There is no significant pathology
	Avoid bed rest
	Not useful for further diagnostic exams
	Learn pain control
	Learn pain management
B	<b>Work and ADL Interventions</b>
	Continue/resume gradually
	Eventually change/reduce work activities
	Control posture
	Reduce for a while physical efforts, if necessary
	Reduce stress
A	<b>Physical Activities Counseling</b>
	Immediately, low impact aerobic physical activity
	Start gradually, preferred physical activity
	Practice regularly, at least twice a week
B	<b>Painkiller Therapy (1–5)</b>
A	Paracetamol with or without opioids
A	NSAIDs
A	Muscle relaxants
C	Manual therapy
C	Physical therapy
C	Pain-kill exercises
B	<b>Expert Multidisciplinary Team Intervention (4–5)</b>
A	Complete diagnostic reevaluation
B	Pain-kill therapies
C	Individual cognitive-behavioral therapy
C	Back school in group (education + exercises)
C	Individual specific exercises
C	Multidisciplinary treatment with workplace inspection

## Notes

1. Painkiller therapy should be proposed only when necessary.
2. Perform a complete treatment.
3. Follow the specific indications of each treatment.
4. Cost-effectiveness priority listing.
5. Choice recommended according to cost-effectiveness, patient preferences, disponibility, and previous results.

In the literature three frequently used models regarding the development and maintenance of CLBP functional limitations are described (140):

- The physical deconditioning model, which assumes that loss of muscle strength, endurance, and aerobic capacity, is responsible for reduced activity levels and hence functional limitations (94).
- The cognitive behavioral model, which postulates that functional limitations result from the maladaptive beliefs and avoidance behaviors that are maintained by learning processes (150,233).

- The biopsychosocial model, which assumes that the loss of functional abilities results from the deconditioning and the cognitive behavioral model (234).

CLBP, as far as we know today, can be defined as a biopsychosocial syndrome (4,12,39) in which all the aspects of the syndrome have developed over time: The patient is enveloped in a series of vicious cycles that emerge from SALBP through a full development of the chronicity risk factors for LBP (see Table 33-1). A simplification of all these processes is represented in Figure 33-6: When pain is not resolved, altered behavioral answers inevitably develop

**FIGURE 33-6.** CLBP patient is enveloped in a series of vicious cycles that emerge from the subacute stage through a full development of the chronicity risk factors for LBP. A simplification (though inevitably complex) of all these processes is represented here.

(4,235,236), even if sometimes these are already present in the patient due to contextual factors (13). Pain also leads to a peripheral and central sensitization that increases pain *per se* (237–241). Moreover, pain can lead to a physical deconditioning, that is, the loss of fitness or dysfunction, meaning altered mobility, strength, endurance, and coordination (93,94,118,127,144,242,243). Finally, long-lasting pain has social consequences because it changes work, familiar and hobby behaviors (145,220,244). All these factors interrelate with each other, leading to a continuous reverberation and redundancy that together increase the problem in all respects, meaning the physical, psychological, and social. Looking at this entire picture, the CLBP patient's lower back simply does not work anymore, partly physically and partly due to the incorrect behavioral and psychological responses. Eventually, this situation leads to social consequences that exacerbate the problem (see Fig. 33-4).

### Clinical Presentation

Usually, a CLBP patient whose pain has persisted for years will present a mix of hope, disappointment, disillusion, fear, and sometimes desperation. Most of the times he or she has already undergone numerous medical examinations, had various diagnoses and faithfully engaged in many therapies, but nothing has been able to solve the problem. When entering your facility, such a person used to say something like, "This is my last hope." In CLBP patients, the pain usually becomes the center of their life. They are so used to experiencing pain that it has become a sort of mate in their everyday life. They think about it every day, and they plan their lives according to the pain behavior and daily cadence. They are not able to imagine a life without pain, and this becomes a sort of preoccupation. Thus, the fear of pain also becomes a mate, since the patient has experienced it so much. Consequently, such a patient develops a fear-avoidance behavior (244,245). It also

happens that limitations due to the fear of pain are much more disabling than the real intensity of the pain. CLBP patients are more sensitive to the risk of feeling pain, so they frequently limit their activities in order to prevent pain. This leads to a "nonuse syndrome," sometimes called deconditioning syndrome (142,246), which is a progressive loss of physical abilities that can maintain and contribute to CLBP (94) even if there is an absence of current data to support this concept (93).

### Diagnosis, Classification, and Prognosis

Again, diagnosis is made by exclusion (see Fig. 33-2). Usually, CLBP patient has already undergone a number of Rx, CT, MRI procedures and many others, so that no further exams are really necessary in order to define a diagnosis. If the chronic situation is quite new and there has been no SALBP evaluation, then this must be done (9). Quite often one will notice that the patient has been to many different MDs, therapists, and health professionals in search of a definitive answer to the problem, and usually such a patient has received as many diagnoses, exams prescriptions, and therapies as there were consultations. Almost every time they are disappointed by the outcome, which has been provisional at best or nothing at worst. Actually, the main reasons for these scant outcomes are inadequate treatments that were merely PO instead of FO therapies.

A major topic in LBP treatment is the attempt to subgroup patients (62,121–124). It is generally agreed that LBP is a common final pathway of many different clinical pictures, of different problems of the back that, complicated by chronicity factors, have led to a more complex clinical situation with a disability sometimes quite important (22). The possibility of subgrouping patients in a reliable way could be the opportunity to provide for each one a more personalized and specific treatment. To date, no subgrouping shared by LBP experts has been made.

A subgroup of CLBP patients has been described using the deconditioning syndrome term, meaning patients in whom the physical aspects of dysfunction and deconditioning prevail (93,94,118,127,144,242,243). Nevertheless, this syndrome is not completely defined. Apparently the more useful approach is to subgroup the patients on the basis of disability (9,21). This is done using specific questionnaires, that is, the Roland Morris (247) (cut-off 14 points (81)) and the "Oswestry Disability Questionnaire" (83) (cut-off 25 points (81)) (see Fig. 33-2). They were designed for LBP patients and are now disseminated worldwide, and have been translated and validated in many languages. The usefulness of this classification relies on the ability and opportunity to choose patients requiring a multidisciplinary approach and those who can be initially treated with a less-expensive approach (9,21).

CLBP resolves completely in very few patients (207). Thus, the patient should be informed about the difficulties in reaching a complete restitution to wellness, and should be provided with tools to manage the problem. There is scientific consensus that the predictors of prolonged disability are more

**TABLE 33.5 CLBP Treatment (9)**

Evidence	Contents
	<b>Aim of Treatment</b>
A*	Chronic pain resolution occurs in <5% of patients. In case of low-disability, aim of treatment is reducing actual disability and avoiding its progression through instruments to manage the problem (active approach by the patient) and control pain
A	<b>Counseling</b>
	There is no significant pathology
	It is difficult to eliminate pain completely
	Pain can be reduced
	It is possible to improve quality of life and reduce disability
	Learn pain management
	Reduce stress
	Be fit
	Work is not enemy
	Physical exercises are important and useful
A	<b>Work and ADL Interventions</b>
	Continue/resume gradually
	Eventually change/reduce work activities
	Control posture
	Reduce stress
A	<b>Physical Activities Counseling</b>
	Start gradually, preferred physical activity
	Practice regularly, at least twice a week
A	<b>Expert Physician Evaluation</b>
	Complete diagnostic reevaluation
	Physical fitness evaluation (biological)
	Behavioral evaluation (psychological)
	Disability evaluation (biopsychosocial)
	<b>Expert Multidisciplinary Team Intervention</b>
	See Table 33-6
B	Chronic LBP therapy changes according to patient disability level (low or high)
C	In case of low-disability, a not-expert approach is possible
C	There is no evidence of efficacy in the literature of a not-expert approach, but it could be preferred in terms of cost/benefit ratio
C	A multidisciplinary approach is complex, nevertheless it is preferable in case of:
	High-disability
	Low-disability but early chronicization (it is still possible to solve the problem)
	Low-disability, no previous trial of this approach and highly motivated patient
C	Multidisciplinary approach is not recommended in case of low-disability and:
	Complex treatment difficult because of cognitive, psychological, or motivational factors
	The patient does not believe in a possible solution

psychosocial than biomedical in nature (77,220,248–250). It has been shown that fear-avoidance beliefs about work and physical activity, catastrophizing the lack of belief in one's own ability to manage pain, cope and function, and self-efficacy beliefs are all significantly related to disability in patients with chronic pain.

### Treatment Approaches

A CLBP patient is a typical rehabilitation patient because of the disability deriving from long-lasting pain (9,21,22). At

this stage the attention should not be centered only on pain, because pain itself is only part of the picture (Table 33-5). It also consists of loss of function, physical deconditioning, and fear-avoidance behaviors. For many years it has been clearly demonstrated that the attention should be focused on function more than on pain (96,251). A PO treatment alone is destined to fail, and usually many different approaches have been proposed and performed without lasting results in each CLBP patient. This point should be clearly explained to patients, since the call for the quickest possible solution to pain

**Notes**

1. Cost-effectiveness priority listing.
2. Choice recommended according to cost-effectiveness, patient preferences, disponibility, and previous results.
3. Painkiller therapy should be proposed only when necessary.
4. Perform a complete treatment.
5. Follow the specific indications of each treatment.
6. Painkiller therapy kills only pain, but is not therapeutic.
7. Only after 2 years of unsuccessful appropriate rehabilitation and according to patient's choice.

Note: For definition of high and low disability, look at the text and Figure 33-2.

is common, and pills are the symbol of every quick solution. A PO therapy can be a useful adjunct to FO rehabilitation, especially in high-disability LBP, but it cannot grant by itself a lasting improvement of pain and disability. Some patients use NSAIDs, muscle relaxants, or sometimes opioids or steroids every day, believing this is the only way to survive pain. Usually, when they try to reduce the amount of drugs they discover their pain is nearly the same. The literature data clearly shows that drugs are effective in CLBP only in the short term, but a psychological addiction can lead to abuse (97,198).

## The Rehabilitative Approach

### Overview

The rehabilitation tools that are effective in CLBP include biopsychosocial inpatient approaches (42), cognitive behavioral approaches (111), exercises of different kinds (126), and educational interventions (109). All these differ in their cost/benefit ratios, even if they have generally been shown to be effective in selected patients. They can be considered as different rehabilitation tools in the hands of the treating physician: the choice of the more adequate depends on individual features of the single patient. There is quite a range of clinical presentations among CLBP patients, since physical deconditioning and dysfunction, fear-avoidance beliefs, social

and psychological factors, and functional limitations can combine in many ways. Therefore, we should choose the less “invasive” and less costly treatment as well as the most effective treatment possible on an individual basis, even if there is no scientific way to distinguish groups of patients according to disability (9).

Regarding high-disability CLBP (9), one should propose as the most effective rehabilitation treatment a cognitive behavioral approach with specific exercises, aimed at recovering the physical limitations of the back, improving function, and giving the patient the right coping strategies. In low-disability CLBP, the suggested intervention is a back school in-group with exercises and education (9); if that does not work, other steps forward include an individual approach with specific exercises, individual cognitive behavioral therapy, and a cognitive behavioral approach with specific exercises (Table 33-6). According to the DTP (9), a higher level of disability justifies the choice of higher cost and individual effort for therapy, while a lower one could benefit from an approach that is generally considered less effective.

### General Guidelines

Despite the foregoing, there are some basic points coming from the literature to be maintained in all CLBP patients, whichever

treatment is proposed. The main claim of a LBP patient is to somehow solve his or her problem, which is nearly constant pain, and hopefully to do it quickly. In the meantime, the patient is not so convinced that a solution is possible, because he/she has already tried many different approaches without achieving a final solution. Because a complete recovery is quite unlikely, even after a long time, the first step of any rehabilitation approach to CLBP should be informing the patient of this prognosis. It should be made clear that the goal of treatment is not to miraculously eliminate the pain but to improve quality of life and reduce the disability by giving the patient the right tools with which to manage CLBP. Obviously, hope must not be erased, but realistic goals must be set at the beginning in order to avoid another disillusion. Moreover, the patient will totally understand that these are realistic goals and the patient himself, due to previous experience, would not believe otherwise.

It has been demonstrated that coping patients have a different response to pain with respect to noncoping patients, who abnormally activate brain areas linked to the emotional processing of pain (237,252–255). Findlay, in a paper presented at the ISSLS Meeting in 2007, has shown that noncopers are “passive patients,” while copers are able to actively manage pain more adequately. It follows that each patient should be the primary actor in his own rehabilitation instead of being part of the audience. Patients are not used to being active during treatments in general, in any disease but in LBP particularly, and sometimes they react by showing disappointment: They want to be taken care of using a pill or a drug, by a physician, or through passive maneuvers by a physiotherapist, a chiropractor, or an osteopath. They want to receive some passive treatments and avoid doing anything independently. Indeed, changing their minds on becoming protagonists of the treatment leads to better results.

Good counseling of the patient can achieve many preliminary good results. The patient should be reassured that he or she has no significant malignant pathology and that even if we cannot completely eliminate pain we can reduce its intensity and decrease the number of acute episodes. Moreover, they must know that managing the situation by becoming copers, reducing physical dysfunction, and deconditioning will lead to a reduced disability and ultimately improve their quality of life. This will allow patient to regain many activities he had once abandoned due to fear avoidance. The patient can gradually start working again and engage in general physical activity, eliminating some of the established vicious cycles (see Fig. 33-6) and instead achieve a virtuous cycle.

The team approach is another important point in this discussion. There is evidence that a multi-professional treatment has the best efficacy in the above cases (42). The psychological attitude of the patient, meaning fear and disbelief, can be best challenged by different professionals who follow the same method and use the same language for progressive reinforcement. Moreover, such patients are by definition multifaceted. They have many different issues to face, and different professionals can give different contributions to solve the puzzle in the best way possible.

### ***Cognitive Behavioral Approach to Physical Exercise***

According to the literature, we envision a cognitive behavioral approach based on specific exercises, since it deals with the psychosocial and physical aspects of CLBP. Moreover, exercises are a very good and accepted way to reach a psychological recovery (110,111,132,134). The fear-avoidance behavior must be faced through a reassuring and courageous challenge to what is considered the main problem: movement. This approach can be used when the patient shows relevant psychosocial and physical limitations without a clear predominance of one aspect over another. The physiotherapist inside the rehabilitation team will choose where to concentrate the efforts according to the individual needs and reactions to treatment, both on the physical (exercises) and psychosocial aspects (counseling). The most typical case in which this approach should be the gold standard is the high-disability CLBP patient (see Table 33-6) (9). Usually in these patients, physical impairment is strictly connected to psychological and social limitations, so there is not a clear predominance of one single aspect. A clear causal relationship between these aspects is generally missing, because what we see is the final outcome of a vicious cycle in which pain limits physical activity, thus rendering movements more difficult and painful with each occurrence. Fear-avoidance beliefs are a crucial factor in generating and aggravating this cycle. Social and other elements are always part of the picture, but this sequence is so deeply bound that one cannot find the beginning.

Usually, a long period of outpatient rehabilitation (months) is needed in order to reach a satisfying result (118,119,256); alternative can be inpatient rehabilitation, that nevertheless must be adequately prepared in advance to reach the best results (142,143,243,257). Patients are not very trustful of therapists at the beginning, generally because they have already tried many therapies without significant results. It is very difficult for a patient to clearly understand the difference between this treatment and a general physiotherapy he or she has already experimented. It is necessary to emphasize that this approach is more complex, team-driven, since it also deals with fear-avoidance beliefs and wrong behaviors, which are secondary to long-lasting pain. The patient should feel that the team trusts him and does not think he is crazy or a hypochondriac. Therefore, every professional must balance words and explanations in the proper way. It is highly relevant to this purpose that the cognitive behavioral treatment is performed by a physiotherapist. This makes the patient feel more comfortable, since he is generally not prepared for a real psychologist to handle this part of the treatment.

This approach is quite expensive, both physically and psychologically, and cannot be used in all patients. It is not recommended when cognitive, behavioral, or motivational factors are present or when the patient does not believe in the possibility of a solution (see Table 33-5) (9).

### ***Cognitive Behavioral Approach***

When psychosocial aspects are predominant and the general physical condition and function are almost preserved, we can

choose a simple cognitive behavioral treatment. The difference from the previous one is the lack of a specific physical approach with exercises. Usually, the patient who can benefit from this approach is quite young and has good overall physical function but relevant fear-avoidance beliefs, and is quite upset about LBP and the prospect for the future. Poor information from the media or a physician, who is not fully prepared, along with a general health-related fear or even real hypochondria, can lead this patient to chronicity, despite a physical limitation that, by itself, is not so relevant. The patient needs to be reassured about his/her future and health, and should be encouraged to return to sports without thinking too much about the previous experience of LBP.

### ***Physical-Exercise Approach***

On the other hand, a simple exercise approach that is specifically developed for the patient and is gradually increased (110,120,132,134) can be proposed when the physical aspects are relevant and the psychosocial aspects are less important. Even if a specific psychological treatment is not provided through this approach, the therapist should provide appropriate general counseling about back-related problems. This approach should be proposed to the patient who lacks psychological and social chronicity factors but is physically deconditioned and limited by dysfunction. A typical example is the older patient who does not have particular chronic stigmata but has undergone a relative loss of function consequent upon the progressive decrease in his or her level of physical activity. It is quite difficult for such a patient to start moving again, and often he or she will feel embarrassed about not being used to performing exercises, sports, or physical activity in a gym. Usually these patients achieve good results and recover to a good functional level, but they still need a maintenance protocol that will preserve the benefits.

### ***Cognitive Behavioral Back School***

A back school in-group with exercises and education is the least burdensome rehabilitative approach for CLBP. As with all group treatments, it has the advantage of being less expensive, and it gives the patient a point of comparison by being in contact with other persons with the same problem. The main limitation is that it cannot be as specific as an individual treatment. Nevertheless, it can provide good information and a valid psychosocial support for such patients. Its main indication is low-disability CLBP (see Table 33-6) (9), when the quality of life is not so impaired that a more aggressive treatment would be required. In the case of a high-disability CLBP, this approach can be used too, particularly, when the possibility or opportunity for a stronger treatment is absent.

### ***Conclusion***

Generally, all these rehabilitation tools should last several months in an outpatient setting, or must be intensive in an inpatient one for several weeks. This is the minimum needed to achieve a real change, to stop the progression of chronicity and revert it to some extent, and thereby return to a better quality of life. If specific causes of LBP are not known, a maintenance protocol would not be necessary; however, it is

important to stop the treatment by reducing the medication of the patient, since he must have acquired effective tools with which to manage his problem. The best maintenance protocol is a physical activity, whether general or through specific machines (144), performed regularly a couple of times each week. Loss of maintenance in CLBP can drive to relapses of the problem (144).

Rehabilitative treatments have demonstrated their effectiveness in reducing disability and pain intensity. A precise evaluation of the patient's features can allow the physician to choose the best rehabilitation tool in terms of cost/benefit ratio. Even if the most effective rehabilitation strategy is a multidisciplinary approach with cognitive behavioral treatment including specific exercises, there are cases in which other strategies can be more effective, or perhaps equally effective but less expensive.

## **Secondary LBP**

This section considers the spinal diseases that are recognized as causes of LBP. It must be clearly stated that there is a big difference between imaging diagnosis and clinical diagnosis. According to the actual literature, the clinical diagnosis of secondary LBP should be defined when there are symptoms and signs confirming that the imaging is meaningful and strictly related to the clinical picture (3,8,9,46,52). If this is not the case, the best interpretation of the imaging is the presence of specific risk factors for the problems. In contrast, the worst interpretation of the imaging finding is giving to the patient a "diagnostic label" (165,166) that can propel him toward chronicization.

## **Sciatica and DH**

As with LBP, the approach to sciatica has also changed with time: if at the clinical evaluation there are no neurologic signs (weakness, ipo/anesthesia, loss of reflexes, radicular impingement), only subacute sciatica is managed differently from LBP (9) (see Fig. 33-2). Consequently, this paragraph will consider subacute sciatica and DH (Figs. 33-6 and 33-7).

### **Definition and Pathogenesis**

Sciatica is generally defined as a pain in the lower back and hip, radiating in the distribution of the sciatic nerve (258). It affects many people, and the annual prevalence of disc-related sciatica in the general population is estimated at 2.2% (259).

Sciatica, in the majority of cases, is caused by irritation of the sensory root or dorsal root ganglion of a spinal nerve. A conflict between the intervertebral disk and the nearby neural structures is the origin of irritation, but lumbar stenosis and tumors are other possible causes (46). When irritation arises, it causes ectopic nerve impulses, which are perceived as pain in the distribution of the axon.

There are two distinctive but not mutually exclusive pathomechanisms for neural irritation. First, the nerve roots, which are subject to sustained compression for long periods, may become sensitized to mechanical stimulation and show pathological changes such as focal demyelination, intraneural edema, Wallerian degeneration, and axonal damage

FIGURE 33-7. DH diagnostic flowchart (9).

(260). Secondly, the irritation of the nerve might occur for a chemically mediated noncellular inflammatory reaction due to the perineural spread of nucleus pulposus, which is inflammatory and leukotactic (95,261).

### Clinical Presentation

The typical clinical picture of sciatica is radicular pain: a deep, severe pain that starts low on one side of the back and then shoots down the buttock and leg when certain movements are attempted. Radicular pain is perceived in the territory innervated by the affected nerve root in the lower extremity when L4/5/S1 nerve roots are involved, or in the anterior thigh when L2/3 are involved. Pain does not always follow the corresponding dermatomes, so it is sensory loss that indicates the affected segment.

Usually, lumbar radicular pain travels through the lower limb along a narrow band. It is perceived as sharp, shooting, or lancinating. It can be experienced superficially and deeply, worsens with coughing and other maneuvers that increase the pressure around the nerve, and radiates to the foot.

The pain is usually worse with prolonged sitting and standing. Bending backward can also increase the pain.

The lumbar spine may present an altered range of motion with limited forward flexion and spasm of the paraspinal muscles. Occasionally, the somatic pain can exist as a dull, aching pain.

If axonal damage is severe, weakness in the leg or the foot may occur, leading to neurogenic claudication. When there is bladder dysfunction with urinary retention or overflow incontinence, saddle anesthesia, and unilateral or bilateral leg pain and weakness, a cauda equina syndrome is present.

### Diagnosis, Classification, and Prognosis

Sciatica is mainly diagnosed through history-taking and physical examination (see Figs. 33-2, 33-5, and 33-7). By definition, the patient mentions radiating pain in the leg and may also report sensory symptoms. Occasionally, the patient will also have LBP, but this is usually less severe than the leg pain.

The first task of medical history and the physical examination is to rule out the suspicions of tumor, infection, significant trauma, or dangerous nonspinal pathology mimicking a back problem. The red flags are a list of relevant risk factors and signs by which an underlying severe disease (262) can be suspected.

A severe neurologic compromise, limping or coordination problems, severe guarding of lumbar motion on all

planes, vertebral point tenderness to palpation, or spinal-cord dysfunction are the most relevant findings in the physical examination, which may suggest relevant underlying diseases.

The neurologic examination can focus on a few tests that seek evidence of nerve-root impairment, peripheral neuropathy, or spinal cord dysfunction.

More than 90% of all clinically significant lower extremity radiculopathy is due to DH and involves the L5 or S1 nerve root at the L4-5 or L5-S1 disc level.

The neurologic examination includes sensory examination, testing for muscle strength and trophism, reflexes, and clinical tests for sciatic tension.

Sensory examination is performed by testing with a light touch or pressure in the medial (L4), dorsal (L5), and lateral (S1) aspects of the foot. Muscle strength is tested through the patient's ability to toe-walk (calf muscles, mostly the S1 nerve root), heel-walk (ankle and toe dorsiflexor muscles, L5 and some L4 nerve roots), or perform a single squat-and-rise (quadriceps muscles, mostly L4 nerve root). Muscle atrophy can be detected through circumferential measurements of the calf and thigh bilaterally, and the difference may be significant when there is a difference of more than 2 cm in the measurements of the two limbs at the same level.

Reflexes may test the S1 nerve root (ankle jerk reflex) or the L4 nerve root (knee jerk reflex). Up-going toes, in response to stroking the plantar footpad (Babinski or plantar response), may indicate upper motor neuron abnormalities (such as myelopathy or demyelinating disease).

The SLR test can detect tension in the L5 and/or S1 nerve root. SLR may reproduce leg pain by stretching the nerve roots. Pain below the knee at less than 70 degrees of SLR, aggravated by dorsiflexion of the ankle and relieved by ankle plantar flexion or external limb rotation, is suggestive of tension in the L5 or S1 nerve root related to DH.

Because the sensitivity of the SLR test is estimated as 91% with a corresponding specificity of 26%, if a patient reports the typical radiating pain in one leg combined with a positive result on one or more neurologic tests indicating nerve root tension or neurologic deficit, the diagnosis of sciatica is justified (46).

Regarding acute sciatica, imaging may be indicated if the results influence further management or infer the suspicion of an underlying disease (infections, malignancies) rather than

DH. Diagnostic imaging may also be indicated in patients with severe symptoms who fail to respond to conservative care after 6 to 8 weeks (46).

The clinical course of acute sciatica is favorable and most pain and related disability resolves within few weeks. Therefore, in most cases the prognosis is good, but at the same time up to 30% of patients continue to have pain for at least a year (46).

### Surgical Treatment: Indication and Limits

The broad consensus is that a cauda equina syndrome is an absolute indication for immediate surgery, but the surgical treatment of sciatica is still a matter of debate. Its goal is to remove DH and eventually part of the disc or foraminal stenosis, thereby eliminating the suspected cause of the sciatica. Surgery may relieve leg pain, but it has no effect on LBP.

Recently, an extensive trial including 1,244 patients compared surgery to medical treatment: 501 patients participated in a RCT and 743 in a prospective cohort study in which patients chose either surgery or medical treatment (263,264).

Unfortunately, in the randomized controlled trial, adherence to the assigned treatment was limited. Within the first 3 months 30% of patients in the medical group had undergone surgery, whereas 50% of patients in the surgical group had improved to such an extent that surgery was not performed. Consequently, no definitive conclusion can be drawn from the study, since it merely suggests that surgery may effectively relieve the pain without affecting the overall outcome (263).

In the observational cohort study, patients who chose surgery had better outcomes at 3 and 12 months than those in the medical-treatment group for all the evaluation criteria, despite the fact that they had more factors of adverse prognostic significance than the medical-treatment group (264). Even in this case a definitive conclusion cannot be drawn due to the limitations of this uncontrolled study.

Finally, a recent updated Cochrane review on surgical interventions for lumbar disc prolapse has stated that surgical discectomy for carefully selected patients with sciatica due to lumbar disc prolapse provides more rapid relief from the acute attack than conservative management, although any positive or negative effect on the lifetime natural history of the underlying disc disease remain unclear (265).

Surgery, in conclusion, appears more suitable for the small percentage of patients with uncontrolled pain or deteriorating neurologic symptoms.

### Rehabilitative Approach

DH was, for years, thought of as a disease of surgical interest. Only recently has proof been accumulated to show that spontaneous recovery is common, many times with improvement of the DH itself (266–269). This has also been proved in the context of specific approaches to rehabilitation (270). In the meantime, proof has accumulated that DH is also quite common in asymptomatic people (266,269), leading to a different understanding of the sciatica symptom: Nowadays an imaging technique is not considered useful in the first month of

3. Perform a complete treatment.
4. Follow the specific indications of each treatment.
5. Cost-effectiveness priority listing.
6. Choice recommended according to cost-effectiveness, patient preferences, disponibility, and previous results.

symptoms (acute sciatica) if the neurologic symptoms are mild or absent, because the spontaneous evolution can be rapid and in most cases auto-resolving (8,9,46). This means it is necessary to understand which kind of rehabilitation program could be most useful in such patients, and now some studies are underway regarding specific conservative and rehabilitative treatments (62,270,271) (Table 33-7).

### PO Approaches

PO treatment is certainly a first choice in these cases, where usually we confront important neurologic pain. According to the actual evidence, we have some proof of efficacy for NSAIDS (97) and short periods of bed rest (107). On the other hand, even without the existence today of any real evidence, manual therapies and manipulation, physical therapies, bed rest for

long periods of time, and steroids are commonly employed. The choice of the type of PO treatment in these cases should follow a progression to be chosen according to the individual risk/benefit ratio and the patient's preferences.

### ***Anti-inflammatory Treatment***

Anti-inflammatory treatment could have a crucial role in DH. This role could go beyond what is usually thought, even with the future discovery of major point that could raise some caution issues. In the past the main pathoanatomical hypothesis for sciatica in the context of a DH was compression, but in the last decade the inflammatory hypothesis has gradually become more significant and today appears to prevail (272,273). Consequently, the research on new drugs is flourishing and could in the near future lead to new advancements. Also, we know the resorption of DH is highest in the worst situations, such as in big DHs and sequestered fragments, both in terms of natural history (268) and as a consequence of treatment (270). Therefore, even if these are usually the most painful situations and have the most frequent neurologic involvement, if the latter is not so important that it motivates surgery, the prognosis is the best one. What must be considered in this context is that DH resorption is presumably led by inflammation through the activation of macrophages (273–277). If this be the case, what is the true role of an anti-inflammatory treatment? On one hand, it could help reduce the immediate neurologic damage, but on the other it could also delay or even impede the spontaneous process of DH resorption (278–280). Obviously, these points will be considered in future research, and today the choice of such a treatment should be based on what we know, namely the pain-killing function of NSAIDs. Other more specific anti-inflammatory drugs are still being researched (e.g., infliximab (274,281)) or lack proof of efficacy, such as steroids both in general administration and locally through infiltration (92,198,282,283).

### ***Rehabilitation and/or PO/ Anti-inflammatory Exercises***

Considering the various types of rehabilitation strategies, again we must think about what they really do. In fact, there are some exercise treatments that are proposed mainly in terms of a PO approach (63), while other strategies such as education and cognitive behavioral support have broader objectives. In any case, confronting with a DH and an acute sciatica is a disease-oriented treatment more than a biopsychosocial rehabilitative approach. Accordingly, a conservative treatment spine expert could be the specialist to consider, and these many times are PRM doctors. Therefore, it relates to our field, but we have to understand what we are really doing, meaning whether it is a FO rehabilitation or a PO treatment.

Research on rehabilitation is in the earliest stage, and recently a systematic review was concluded with the absence of any real evidence (282). When compared to surgery, rehabilitation has almost always been proposed in terms of “standard care” (263–265), an expression that means nothing more than “whatever a more or less expert physiotherapist wanted/

was able to offer.” The same occurred in a RCT comparing physiotherapy to bed rest and the continuation of ADL, which showed that neither of the two interventions had any effect (284). We cannot rely on such methodologies as the means to understand something real. In a retrospective review of patients with good results, mobilization and general exercises have shown better efficacy than spasm-reduction interventions (285). In the literature we cannot find much data, due to the fact that this field of research is very young.

The McKenzie approach (61–63,286) is a physiotherapy method that theoretically focused on DH or, better, on disk behavior as the possible source of all LBP problems. The main merits of this method include the discovery of the importance of the centralization phenomenon (61,125,287,288) and the discovery and systematization of a mechanical diagnosis to individualize exercises according to pain behavior (62). Centralization is the response of pain that occurs with repeated movements, such pain moving toward the midline and the back. It is a prognostic factor and a determinant clue to develop pain-killing exercises (61,125,287,288). The subclassification of McKenzie, stemming from repeated movements and answers of pain, has proved important in terms of exercise choice (62), and today it is used by others in their own development of subclassification methods (121,123). This technique has not yet provided definitive answers on its efficacy (63), but it must be looked carefully as a possible pain-killing tool with the advantage of being administered by a physiotherapist who could also offer other rehabilitative advice. Obviously cost is the main limitation, as compared to other PO treatments.

According to the DH pathophysiology and natural history, the first objective of rehabilitation—when facing an acute sciatica and/or a DH trying to avoid surgery—should be to help spontaneous resorption, and if possible to increase the speed of this process. On the other hand, one must avoid increasing pain and the problem itself. In this respect movement is known as a means to increase bloodflow: consequently, whichever movement that does not increase pain or tissue damage can be useful to accelerate the wash-out of the inflammatory and proteolytic enzymes while increasing oxygenation, nutrient capitation, and the arrival of macrophages, thereby reducing inflammation and facilitating a rapid DH resorption. Accordingly, the McKenzie approach, more than being a way to mechanically drive the disk back into position, could be a way to mobilize the spine and symptomatic disk without causing an increase in pain. Therefore, it could facilitate an immediate wash-out of inflammatory agents and a progressive reduction of the pathological situation. If this is true, it could explain why the physiotherapy approach that showed the best results in a retrospective analysis of sciatica treatment was joint mobilization (285).

Setting aside any other consideration, central to a rehabilitation approach to DH is education and a cognitive behavioral counseling with the goal of encouraging DH resorption and reducing the risk of increased symptoms, but also of chronicization and ultimately increasing the patient's self-care.

**FIGURE 33-8.** Severe stenosis of the spine. CT scan image showing central stenosis by congenital pedicle shortness and facet degenerative hypertrophy.

Knowing what to do and what to avoid should always be part of a complete treatment in these cases, but if we also add what can be expected in the near future and beyond—meaning what a DH is and what its prognosis is—the fact that DH is not a chronic condition but an acute one, etc., will be a sure help for the patient (9). Moreover, in the case of neurologic damage the patient must clearly understand the timing of recovery and what it can mean to his or her everyday life.

A good approach to DH should, therefore, include a PO treatment combined with joint mobilization and/or active exercises performed in a pain-free way, looking for the centralization of symptoms so as to speed up the autonomous and spontaneous recovery of the situation. Counseling and information are crucial, as are work and ADL interventions. This will stand until we have more data regarding what should be done.

## Lumbar Spinal Stenosis

### Definition and Pathogenesis

LSS is defined as any type of narrowing of the lumbar spinal canal, causing compression of its content (Fig. 33-8). This narrowing causes direct mechanical compression on the neural elements or on their blood supply, which may lead to symptoms (289,290). The symptoms can decrease the patient's quality of life and cause him or her to seek treatment.

LSS may occur at different places in the spinal canal, sometimes in more than one location at the same time. In central canal stenosis, the nerve roots in the cauda equina may be compressed. Lateral recess stenosis and foraminal stenosis may cause compression of the nerve roots leaving the spine (291,292).

The presence of a narrow canal in radiographic imaging does not define the syndrome. Instead, a diagnosis of LSS is defined by symptoms and clinical findings that must be supported by radiographic evidence.

LSS results from degenerative, developmental, or congenital disorders. The degenerative type is often due to arthritic changes: Disc degeneration, facet degeneration and hypertrophy, degenerative spondylolisthesis (SL) and ligamentum flavum hypertrophy, and calcification can cause LSS alone or in combination, or can further compromise the space of canal that is already small (293,294). The degenerative type occurs most often, particularly in patients over 50 years of age (290,291,294,295). The congenital type may occur earlier in life, and LSS is a result of congenitally anatomic changes or malformations, for example, an excessive scoliosis or excessive lordotic curvature (289,290,295). Developmental LSS is a condition in which the narrow spinal canal is caused by a growth disturbance of the posterior elements (296).

### Clinical Presentation

LSS patients frequently present with few objective physical findings. Approximately 65% of patients have decreased walking ability, but up to 95% of patients treated surgically have only subjective symptoms, chiefly pain (297–299).

Patients with LSS report three types of complaints: LBP, leg symptoms, and neurogenic claudication. LBP is indistinguishable from nonspecific LBP. Leg symptoms are due to a radiculopathy with an aching or sharp pain and/or symptoms of pain, burning, numbness, and paresthesia following a specific dermatomal distribution in one lower extremity. The fifth lumbar nerve root associated with L5 stenosis is most often involved in this type of LSS (300).

Regarding neurogenic claudication, patients complain of cramping, weakness, pain, numbness, and tingling. These do not follow a specific dermatomal distribution but are most often experienced in both lower extremities. Occasionally, the patient will complain of bladder dysfunction and sexual difficulties. In LSS with less dermatomally specific neurogenic claudication, nerve roots below L5 are most commonly involved (300). In several patients, radiculopathy and neurogenic claudication coexist in a mixed type of LSS (300,301). Full-blown cauda equina syndrome only occurs in rare instances (140).

Because both the central canal and foraminal dimensions increase in flexion and diminish in extension, patients with LSS experience the exacerbation of symptoms with extension and improvement with flexion, meaning the symptoms are provoked by the act of standing but relieved when the patient is seated.

### Diagnosis, Classification, and Prognosis

The tendency in diagnosing LSS is to focus on imaging studies (Fig. 33-9). However, it has been reported that in approximately 30% of asymptomatic subjects lumbar spinal abnormalities can be seen on imaging studies (302–304). In asymptomatic individuals, 60-years-old or more, LSS was detected on MRI in 21% of cases by Boden et al. (303). In a study by Jensen et al the percentages of spinal abnormalities over 30% were reported (269).

Due to the discrepancies between clinical symptoms and imaging findings (296,305), there is a difference between the

FIGURE 33-9. Spinal stenosis diagnostic flowchart (9).

clinical and radiologic diagnosis of LSS. Therefore, clinical and radiologic findings should be considered together when diagnosing this disease.

Regarding patient history, the key factors that seem most strongly associated with the diagnosis of LSS are a higher age, severe pain in the lower extremities, and the absence of pain when seated (306). The physical findings most strongly associated with the diagnosis were a wide-based gait, an abnormal Romberg test, thigh pain following 30 seconds of lumbar extension, and neuromuscular deficit (306). Treadmill walking is also useful for diagnosis: a combination of time to onset of symptoms and recovery time after treadmill walking, or a longer walking time during inclined treadmill walking are suggestive of LSS (307). A combination of these key diagnostic factors has been proposed as a diagnostic algorithm for clinical practice to assess the likelihood of LSS, to guide and facilitate the clinical decision-making process (306,308–310).

Once the diagnosis of LSS is suspected due to history and clinical findings, the anatomical structures can be evaluated through CT or MRI, which, in a recent meta-analysis, seem to have comparable accuracy. Myelography should be avoided due to its invasiveness and lack of superior accuracy versus CT or MRI (307).

Both CT and MRI allow a precise measurement of canal diameter. An anterior-posterior (AP) canal diameter of less than 10 mm constitutes absolute stenosis, whereas an upper limit of less than 13 mm denotes relative stenosis (311–313).

According to a recent study, patients with smaller canals report greater perceived disability, but AP spinal canal diameter was not significantly associated with other clinical symptoms (314).

LSS, in radiological terms, has been classified by the location of the stenosis into central, lateral recess, and foraminal stenosis. Theoretically, central stenosis gives rise to cauda equina

compression and neurogenic claudication, whereas lateral recess (or foraminal) stenosis is associated with radiculopathy.

Electromyography and nerve conduction studies may be useful in the diagnosis of LSS because fibrillation potentials could discriminate clinical LSS from other disorders with excellent specificity, and could detect alternative or comorbid disorders (315).

The few studies of the natural history of LSS generally seem to indicate a relatively benign course (316–320). Anatomy is seldom related to the severity of symptoms and probably other factors come into play. Segmental hypermobility, local neurovascular compromise, venous congestion, foraminal stenosis, or facet joint effusion may explain pain exacerbation and disability. Generally, LSS is a fluctuating syndrome with an overall improvement, and it is in a continuum with LBP and the absence of symptoms.

### Surgical Treatment: Indication and Limits

LSS is the most common reason requiring lumbar spine surgery in adults older than 65 years (321). The patient's subjective experience of disablement must be an important part of the indication for surgery, since anatomic and neurologic deficits do not predict future function (see Fig. 33-9).

The aim of the operation is to improve the quality of life, and surgical candidates include patients who have persistent severe leg symptoms and functional limitations.

Different studies have suggested the benefit of surgery in selected candidates. Atlas et al reported a greater improvement in surgically treated patients compared to nonsurgically treated patients in both the 1- and 4-year evaluations (322,323). Similar results were reported in a prospective 10-year study, in which considerably better treatment results were found in a group of patients randomized for surgical treatment compared to a group randomized for conservative treatment (324).

Additionally, a meta-analysis of the literature showed that an average of 64% of patients treated surgically for LSS were reported to have good to excellent outcomes. Nevertheless, it is important to note that the reoperation rate and failures are relatively high (325); moreover, surgery is only valuable for leg pain while it does not necessarily relieve LBP (283,325,326).

Depression, cardiovascular comorbidity, disorder influencing walking ability, and scoliosis are predictors of poorer subjective outcome after surgery, and they may be considered in the decision-making process for surgical indication (327).

Less aggressive surgical techniques that provide for adequate decompression have recently been reported. These procedures have been described as fenestration, laminotomy, selective decompression and laminarthrectomy, and are purported to improve postoperative morbidity, provide early mobility, and reduce the hospital stay. However, their long-term impact on disability has not been determined.

### Rehabilitative Approach

According to the earlier definition, when a patient has an imaging diagnosis of LSS without any clinical sign, he/she should be considered as carrying a specific risk factor for LBP, but nothing more. In the literature there are studies comparing surgery to the conservative approach, but they are mainly observational, and cross-over between groups due to patient's choice has been quite common. Usually, in the literature the tested rehabilitation programs are not well described (317,322–324). Generally, it is possible to find some “expert opinions” that, in any case, are not in full agreement with one another (322,328–330).

We can consider two main possible exercise approaches to LSS (Table 33-8): One is aimed at directly facing the pathology and trying to achieve improvements with treatment; the other focuses on allowing better management of an already stable situation, even if the possible future increase of problems can be the long-term result. The first protocol should be pursued whenever possible, while the second can be considered when the first one fails.

LSS is partly due to new bone formation and partly due to the thickening of soft tissues (292,311). Only in the latter is it possible to try to allow better bloodflow while walking and avoid (or delay) the development of symptoms. In this respect the elasticity of soft tissues is the main objective, along with guaranteeing the best physiology through appropriate movement. On one hand, this means manual therapy, mobilization techniques (328), and exercises to increase the range of motion, while on the other hand it means neuromotor control, proprioception, strength, and endurance training. In the meantime, achieving a good capability of counteracting gravity force so as to slightly elongate the lumbar spine and provide more space for neural tissues can be another goal of exercises. This can be achieved through postural education and an increased endurance of deep stabilizing muscles, as well as with various activities in elongation. In this regard, specific muscular impairments have been shown in LSS patients (315,331), and these could definitively contribute to the symptoms. In this exercise approach, it is also important to

educate the patient in maintaining a good erect posture while walking, because we are trying to renormalize the pathoanatomic situation as much as possible and avoid a progressively forward-bent posture, which is quite typical of long-standing LSS patients (316).

The other possible program is the one most discussed in the literature (322,328,330), and should be proposed in the worst cases and/or if the previous one fails. By contrast to the previous program, this one aims to increase the gait autonomy by teaching the patient to move in flexion, because flexion increases the space for bloodflow and can allow one to move better than extension in LSS (296,332). This program has been evaluated in the literature and short-term results have been presented (333). Nevertheless, in this case we can ultimately facilitate the progressive flexion of the spine, or we can with time reduce autonomy and require that the patient use a cane to move from one place to the other.

Apart from these specific programs, aerobic training can increase the peripheral oxygen uptake, thereby reducing symptoms and increasing the patient's maximum walking distance (330,334). Another alternative procedure, or eventually a first step toward achieving the programs previously described, can include body-weight support treadmill training (329). Additionally, water-based exercises and traction have been proposed, as well as neural mobilization techniques (328) despite the absence of evidence in the literature. Orthosis and lumbar supports have been proposed, but again no data exist in the literature (328).

As is always the case with LBP patients, counseling is a crucial point (9). Key messages should include knowledge of the pathology, its main symptoms, and its prognosis in terms of pain and the ADL. Particularly, the possible evolution in a flexed posture (FP) must be explained with the aim of avoiding it. Moreover, pain control and prevention are crucial, as are strategies for pain management. ADL can be adapted according to the need, and the use of a bicycle instead of walking is suggested. Or, when needed, the use of a cane could be proposed.

### Lumbar Spine Instability and Spondylolisthesis Definition and Pathogenesis

Instability of the lumbar spine is a controversial topic. Despite several efforts, an accepted definition of lumbar spinal instability (LSI) is not yet available.

A reasonable definition has been proposed by Pope and Panjabi (335) and Frymoyer and Selby (336). Instability can be defined as an abnormal response to applied loads, characterized kinematically by abnormal movement in the motion segment beyond normal constraints (336). This abnormal movement can be explained in terms of damage to the restraining structures (i.e., facet joints, disks, ligaments, and muscles) that, if damaged or lax, will encourage altered equilibrium and thus instability (335).

LSI is considered to represent one of the potential conditions causing nonspecific LBP (335).

Traditionally, the occurrence of SL in subjects with CLBP has been considered one of the most obvious manifestations

## Notes

1. Mobilization means performing repeated maneuvers till the end of ROM that imply an increase of ROM during time.
2. Stabilizing exercises increase spinal neuromotor control ability and are based on the improvement of: proprioception, kinesthesia, spinal coordination precise neuromotor control of movement, strengthening of stabilizing muscles (particularly multifidus and transversus).

**FIGURE 33-10.** Instability of the spine. MRI image of first grade L5-S1 spondylolisthesis with disk degeneration of L3-4, L4-5, and L5-S1.

of LSI (Fig. 33-10) (337,338). Furthermore, several studies (339–341) have reported increased and abnormal intersegmental motion in subjects with CLBP and in the absence of other radiological findings.

### Clinical Presentation

Nonspecific LBP and sciatica are the most frequent clinical presentations of LSI and SL. Higher incidences of SL might be seen in people involved in repetitious alternate loading activities such as gymnastics, weightlifting, and football.

Numerous anamnestic and clinical findings are proposed to suggest instability: frequent recurrent episodes of LBP, short-term relief from manipulation, a history of trauma, improvement of symptoms with a rigid brace or external fixation, palpation for the presence of a “step-off” between adjacent spinous processes, aberrant motions such as an “instability catch,” or increased mobility with passive intervertebral motion testing. Generally, the validity of these findings has not been reported.

Recently, a questionnaire completed by patients diagnosed with LSI described back pain symptoms as “recurrent” (70%), “constant” (55%), “catching” (45%), “locking” (20%), “giving way” (20%), and/or “accompanied by a feeling of instability” (35%) (342).

Data by subjects diagnosed with LSI involved in recent clinical trials revealed that half of the subjects developed their LBP condition secondary to a single event injury while the other half developed LBP gradually in relation to multiple minor traumatic incidents (343).

In another questionnaire completed by physical therapists, identification of muscle dysfunction, motor control abnormalities, and loss of strength were the greatest indicators of clinical lumbar instability. The descriptors of poor lumbo-pelvic control include segmental hinging or pivoting with movement, muscle guarding/spasm, poor coordination/neuromuscular control, decreased strength and endurance of local muscles at the level of segmental instability were the top three component scores (342).

In another study the two most predictive factors of radiographic instability from the history and physical examination were lumbar flexion ROM and a lack of hypomobility during lumbar intervertebral motion testing. The presence of both findings increased the probability of instability from 50% to 93% (69).

In a recent study about the correlation between LSI and clinical symptoms, the translation of the lumbar segment had a greater influence than angulation on lumbar symptoms, and the combination of translation and angulation was associated with worse symptoms and the persistence of pain (344).

### Diagnosis, Classification, and Prognosis

A systematic clinical history and physical examination should be performed to characterize the LBP, distinguish referred from radicular symptoms, document sagittal alignment and spinal mobility, and establish the presence of any neurologic deficit, paying particular attention to the function of the nerve roots exiting at the level of the olisthetic vertebrae (Fig. 33-11).

Spine instability may be classified into two categories: radiologic appreciable instability and clinical instability. Radiologic instability reflects marked disruption of passive osseoligamentous anatomical constraints, as in the case of spondylolisthesis. Clinical instability is more challenging to diagnose and may involve discrepancies in radiographic findings.

The imaging analysis begins with conventional radiology, with anteroposterior, lateral, and flexion-extension radiographs. A number of radiographic indices can be made from the standing lateral radiograph, including the degree of slippage, slip angle, sacral inclination, sacrohorizontal angle, and lumbar index. CT and MRI are useful advanced imaging methods, particularly in the preoperative planning stage, for better defining both the bony and soft tissue anatomy, respectively.

Note

1. Over 3 mm of mobility or over 10° of intervertebral angle.

**FIGURE 33-11.** Spinal instability and spondylolisthesis diagnostic flowchart (9).

Knutsson originally described a method for diagnosing segmental instability using lateral radiographs with the patient performing maximum lumbar flexion and extension (345). The amount of sagittal plane translation and rotation occurring at individual spinal motion segments are calculated (346–348).

White and Panjabi defined criteria for diagnosing instability from flexion-extension radiographs as sagittal plane translation greater than 4.5 mm or greater than 15% of the vertebral body width, or sagittal plane rotation greater than 15 degrees at L1/L2, L2/L3 or L3/L4, greater than 20 degrees at L4/L5, or greater than 25 degrees at L5/S1 (349). Although concerns about the validity of flexion-extension radiographs have been raised (350,351), this method has become the standard by which lumbar instability is diagnosed.

At the lumbosacral junction, stability is dependent on the spatial orientation of L5 to the sacrum, lumbosacral angle, sacral slope, and pelvic incidence as well as an intact osteo-discal-ligamentous complex. Because spinal parameters are dependent on pelvic parameters, alterations in local spatial orientation, such as SL, can produce global spinal imbalance. Some spondylolistheses progress to severe deformity, while others progress very little. The pelvic incidence seems to be one of the most important factors linked with a higher degree of slippage.

Given the aging population, degenerative SL is getting more and more common. It occurs in individuals older than 50 years, it occurs four times more frequently in women, and is most commonly seen at L4-5 (352–354). Rarely, however, does the slip exceed 25% to 30% of the width of the subjacent vertebra (355).

### Surgical Treatment: Indication and Limits

Management decisions for adults with LSI need to take into account the severity and duration of symptoms and patient comorbidities. Those patients with intolerable back and/or leg pain recalcitrant to a prolonged conservative treatment program could be candidates for surgery (see Fig. 33-11).

In patients with SL, progression of the slippage occurred only in about 30% of cases. Over 70% of the patients who were initially neurologically intact did not deteriorate over time and these patients may be treated conservatively. Conversely, most patients with a history of neurogenic claudication or vesicorectal symptoms deteriorated with poor final outcome and these patients should preferably have surgical treatment (353).

In case of SL, indications for surgical treatment are persistent or recurrent back and/or leg pain or neurogenic claudication, with significant reduction of quality of life, despite at least 3 months of nonoperative treatment, progressive neurologic deficit, or bladder or bowel symptoms (356).

Because there is no consensus as to what constitutes the optimal surgical treatment or what constitutes the more appropriate nonoperative program, the decision to recommend surgical treatment to an adult patient with LSI must be carefully individualized.

Spine fusion is the selected procedure for LSI. It was initially performed to stabilize vertebral fractures, spinal tuberculosis, and deformities such as scoliosis. In recent years, however, a majority has been performed for degenerative spinal conditions. The rationale for fusion is that it should reduce abnormal motion and, therefore, reduce pain. The efficacy of fusion in this context remains uncertain (357–359).

Regarding SL, the mainstay of surgical treatment is decompression and there is no general agreement about the indications for fusion and instrumentation. The goals for decompression are to relieve radicular symptoms and neurogenic claudication, the goals for fusion are to relieve LBP by elimination of instability, and the goals for instrumentation are to promote fusion and to correct listhesis or kyphotic deformity.

Two considerations rise doubts on the efficiency of surgery. First, the long-term outcome of surgery is uncertain: most studies are predominantly retrospective and most certainly describe a wide variety of surgical indications and surgical techniques. Second, the reoperation rate: in a recent study among over 24,000 patients after lumbar surgery the 11-year cumulative incidence of reoperation was 19.0% with a higher incidence among patients whose initial operation involved a fusion (360).

### Rehabilitative Approach

An important contribution to understand clinical instability was provided by Panjabi (361), who proposed the existence of three separate but interrelated subsystem that act to control intersegmental spine stability: the passive subsystem (e.g., ligaments, vertebrae, disks), the active subsystem (musculature), and the neural subsystem (e.g., sensory receptors, cortical, and subcortical controls). Instability can result from a deficit in one of these components and, according to Panjabi's (362) definition it consists in a significant decrease in the capacity of the stabilizing system to maintain the intervertebral neutral zones within the physiological limits. The intervertebral neutral zone (362) is the zone, within the "range of motion," of high flexibility, laxity within which the spinal motion is produced with minimal internal resistance. The components of the stabilizing system are functionally (363) interdependent so that compensation for system dysfunction may occur. Instability could be a result of tissue damage, making the segment more difficult to stabilize, insufficient muscular strength or endurance, or poor muscular control; instability is usually a combination of all three. This is the ratio for rehabilitation program in the patient with spinal instability due whether to a functional, neuromuscular instability, or SL (see Table 33-8). The major source of spinal stability and the component that can be enhanced from a rehabilitation approach is the second one (364), meaning the musculature, which appears particularly effective in the neutral zone, when passive structures assume only a minor role. Trunk stabilizing muscles are also defined as a core stabilizing system that is described (364) like a box with the diaphragm on top, pelvic floor on bottom, abdominals in front, and paraspinal and gluteal muscles in back. Core musculature is required for the spine (365) to move freely throughout its entire range of motion, and it also serves as a functional center of the kinetic chain by connecting the upper and lower extremities. This musculature is divided in the local deep unisegmental muscle (366) (transversus abdominis and multifidus) whose function consists mainly in stabilization, and global, superficial, multisegmental muscles (external oblique, erector spinae, rectus abdominis, psoas)

intended mainly to produce control movement of the trunk. Moreover, in healthy individuals, fibers of the multifidus and transversus abdominis are the first fibers to become active when a limb is moved in response to visual stimulus (367), and the timing of superficial fiber activation depends also on the direction the limb is moved to assist with control of spinal orientation. Nevertheless, the neuromuscular subsystem coordinates muscle activity to respond to both expected and unexpected forces. This system must activate the correct muscle at the right time (368) by the right amount to protect the spine from injury and also allow the desired movement. Poor neuromuscular control may explain the onset of ALBP (363,369), even though there is no external load. Pain may be due to an adjustment mistake by one or more muscle in terms of magnitude and timing of responses caused by faulty afferent information.

In the acute phase, the first aim consists in providing a good control of pain (370) by pharmacological treatment or physical modalities and some easy exercises to minimize pain, avoiding spinal manipulation or traction; according to cognitive behavioral approach, physician will explain what is happening to the spine (distinguishing between a mechanical instability, due for example to a SL or a neuromuscular one; informing patient that the degenerative SL natural history shows an improvement as the disc space collapses and progression of the slippage occurred only in 34% of the cases), what patient can do to manage pain instead of undergo it. It is also useful teaching to avoid heavy and sudden loads, and extreme flexion and extension movement of the spine; patients with SL must know the risk factors of worsening (like hyperextension movements, high level physical activity), and main problems that may present like nerve-root pain, neurologic claudication. An aerobic conditioning will be encouraged, such as swimming, walking, or stationary bicycling that promotes spinal flexion and avoid wear and tear associated with impact aerobic exercises such as running (370). Lumbar support may be used in the acute phase only a few hours per day in order to help spine to support itself, but with the beginning of stabilizing exercises it will gradually be removed. A rigid brace (371), in selected cases of SL, can provide a way to control worsening of listhesis and sometimes also a reduction.

In the chronic phase, treatment consists of an intensive continuous stabilizing program (Fig. 33-12) with a deep cognitive behavioral intervention. Lumbar stabilization exercises aim (363) at a sensorimotor reprogramming of the spine stabilizer muscle intended to improve their motor control skills and delay of response, and consequently to compensate for weakness of the passive stabilization system. Stiffness is achieved with specific patterns of muscle activity, which differ depending on the position of the joint and the load on the spine. Core muscle endurance seems to be more important than total strength (67). This is due to the fact that in normal circumstances only a small amount (approximately 10% of maximal contraction) is needed to provide segmental stability. The first phase of the exercise program previews specific

**FIGURE 33-12.** Stabilizing exercises. **A:** Strengthening of back muscles to improve spine stabilization function. **B:** In this exercise loss of pelvis support allows to excite stabilization muscles complex.

isometric transversus abdominis-multifidus co-contractions (364), while maintaining the spine in a static neutral position. Exercises are based on the drawing-in action, called abdominal hollowing, presented by Richardson (364) who recommends performing exercises for 10 minutes ten times a day, while maintaining a normal breath. It can be performed by abdominal hollowing in a prone position, eventually with diagonal elevation of the arm and leg, or in a four-point kneeling position, which facilitates maintenance of neutral lordosis and a sensation of transversus abdominis muscle contraction. Therapist will use techniques of facilitation such as muscular palpation or visual feedback. The second stage requires co-contraction in situation where patients feel “unstable,” experience or anticipate pain. The third stage of training includes functional demands of daily requiring a low degree of attention for adequate contraction. However, exercises can then progress from training isolated muscle to training the core as an integrated unit to facilitate functional activity. The neutral spine, considered like a pain-free position that is touted as the position of power and balance, has been advocated as a safe place to begin exercises. Neuromuscular control can be enhanced through a combination of joint stability (co-contraction) exercises, balance training, perturbation (proprioceptive) training, polymeric (jump) and also via wobble boards, roller boards, and physio-ball. O’Sullivan et al. (372) found that individuals with CLBP and a radiological diagnosis of SL, who underwent a 10-week specific exercise program, showed a statistically significant reduction in pain intensity and functional disability levels, which was maintained at 30-month follow-up.

## Vertebral Deformities in Adults

### Definition and Pathogenesis

The ageing spine might develop two characteristic deformities: scoliosis and FP. Scoliosis in the adult is a disorder that involves a convergence of deformity and degenerative disease in the spine. It is defined as a spinal deformity in a skeletally mature patient with a Cobb angle of more than 10 degrees in the coronal plain (373). Independently from this definition, scoliosis can worsen in adulthood when it exceeds 30 degrees Cobb, and this evolution is almost certainly more than 50 degrees (374–378). The pathomechanism in these cases of AS is quite predictable: The primum movens is an asymmetric load or degeneration. Asymmetric degeneration leads to increased asymmetric load and therefore to a progression of the degeneration and deformity. The progression of a curve might be further supported by osteoporosis, particularly in postmenopausal women. The destruction of facet joints, joint capsules, discs, and ligaments may create monosegmental or multisegmental instability and finally LSS. There is also a *de novo* scoliosis (373) directly caused by asymmetric degeneration in a previously straight spine. Even if quite painful, this situation usually does not lead to a wide increase in Cobb angle over time (379).

FP is defined by thoracic kyphosis, protrusion of the head, and in more severe cases, knee flexion. The pathophysiology of FP in the elderly is most likely multifactorial: low bone mineral density, vertebral fractures, intervertebral disk degeneration, and back extensor strength, which decreases with age, are the most frequently encountered factors (380).

### Clinical Presentation

The patient with significant AS may be relatively asymptomatic or severely disabled by his or her deformity.

The most frequent clinical problem of AS is LBP (373,381,382). LBP at the site of the curve can be localized either at the apex, on the prominence/hump, or in its concavity. It can be combined with radicular leg pain. It can be the expression of a muscular fatigue or of a genuine mechanical instability.

When the lumbar curve is accompanied by the loss of lumbar lordosis, the overloaded and stressed paravertebral back muscles may become a source of diffuse, permanent muscular pain. The pain, however, is generally present when the patient is upright, especially when standing and sitting, presenting as a so-called axial LBP, and the patients often indicate that they can control their pain well when lying down flat or on their side, and when the spine is relieved of its axial load.

The second important symptom of AS is radicular pain and claudication symptoms when standing or walking (383). The radicular pain may be due to a localized compression or root traction whereas claudication may be due to single- or multiple-level LSS.

The third important clinical presentation is a real neurologic deficit, including individual roots, several roots, or the whole cauda equina with apparent bladder and rectal sphincter problems. However, an objective neurologic deficit is rare, and when present it is due to a significantly compromised

FIGURE 33-13. AS diagnostic flowchart (9).

space in the spinal canal with relatively acute aggravation and decompensation.

The fourth relevant symptom or sign is a progression of curvature. It usually becomes relevant when the curve has reached a certain degree and/or when osteoporotic asymmetric collapse could be relevant as a contributor to such curvature. Once the curvature has reached a certain degree, the progression will automatically follow due to the axial mechanical overload of individual facet joints and/or osteoporotic vertebral bodies. In case of evolution, usually AS progressively drives the spine laterally and ultimately in anterior flexion in the elderly, causing the need for a cane when walking.

Concerning FP, the kyphotic changes of the spine may cause local pain for vertebral overloading, inappropriate stretching of the ligaments and muscles, as well as overstress on the paravertebral back muscles (380,384). Compensatory hyperlordosis in the lumbar spine can cause LBP and a forward bending posture has been suggested to be associated with sacral and pelvic pain. FP also alters the load distribution on vertebral joint surfaces, leading to an increased spondylosis and vertebral bodies deformities when osteoporosis is present. Patients with severe FP show greater depression, reduced motivation, muscle impairment with a weaker spine extensor and ankle plantar flexor, lower scores in the balance and gait tests, a slower and wider base of support, and diminished ability in the ADL (380).

### Diagnosis, Classification, and Prognosis

The diagnosis of AS is made on conventional x-rays (Fig. 33-13). It is classified into four major groups (373):

*Type 1:* Primary degenerative scoliosis, mostly on the basis of a disc and/or facet joint arthritis, affecting those structures asymmetrically with predominantly LBP symptoms, often accompanied with signs of LSS or without such signs. These curvatures are often classified as *de novo* scoliosis.

*Type 2:* Idiopathic adolescent scoliosis of the thoracic and/or lumbar spine, which progresses in adult life and is usually combined with secondary degeneration and/or imbalance. Such patients may develop secondary degeneration and progression of the adjacent curve.

*Type 3a:* Secondary adult curvature in the context of an oblique pelvis, for example, due to a leg length discrepancy or hip pathology, or as a secondary curve in idiopathic; as neuromuscular and congenital scoliosis or as asymmetrical anomalies at the lumbosacral junction.

*Type 3b:* Secondary adult curvature in the context of a metabolic bone disease (mostly osteoporosis) combined with asymmetric arthritic disease and/or vertebral fractures.

In AS, sagittal balance seems to be the most important and reliable radiographic predictor of clinical health status, as patients with positive sagittal imbalance report worse self-assessment in pain, function, and self-image domains (384). Age also influences the natural history of AS. Thoracic kyphosis increases with age, whereas lumbar lordosis decreases, leading to a net effect trending toward positive global sagittal balance with advancing age (385,386).

Coronal imbalance seems to be associated with deterioration in pain and function scores for nonoperated patients, but only when it is greater than 4 cm (384).

Other radiographic parameters correlated with pain in AS were lateral vertebral olisthy, L3 and L4 endplate obliquity angles, lumbar lordosis, and thoracolumbar kyphosis (387).

Beyond the standard clinical examination, patients with symptomatic AS may sometimes require interventional radiological procedures, such as sequential discograms, facet blocks, and epidural blocks to evaluate pain source. Finally, in elderly people with degenerative scoliosis and symptoms of claudication, leg pain and multilevel LSS, motor evoked potentials (MEP) may be helpful to identify the level responsible for the clinical presentation.

Regarding FP, kyphosis and vertebral deformities could be evaluated on lateral conventional x-rays. Kyphosis is measured by the traditional Cobb angle where the angle is derived from the slope of the superior vertebral endplate of T4 and the inferior vertebral endplate of T9.

Intervening vertebral deformity could be quantified by morphometry, which compares the height of the anterior, middle, and posterior parts of each individual vertebral body. When one of these heights is more than 20% lower than one of the other heights, the occurrence of a vertebral fracture is assumed (388). Because the number and the severity of vertebral fractures are both of prognostic value regarding pain, disability and risk of further fractures, a cumulative semi-quantitative index of the number and severity of vertebral deformities occurring between T4 and L5 has been developed (389,390).

### Surgical Treatment: Indication and Limits

In AS and FP, surgery is an extreme option when the nonsurgical measures have no effect or do not promise any relevant long-term improvement.

Planning the surgical procedure requires a clear understanding of the prominent symptoms or clinical signs, and it is also influenced by the patient's general health, age, conditions of bone quality, and the patient's expectations.

The possible surgical technique can be divided into posterior, anterior, or combined procedures. In all these procedures, a simple decompression or stabilization can be done, or both can be combined. In some cases, additional correction may be performed by osteotomies or by sequential segmental correction through instrumentation (373).

Spinal surgery in these conditions is very demanding because it frequently deals with fragile elderly with poor bone quality. In these cases, reoperation rate and complications are significantly above the average for spinal surgery (373,391,392).

### Rehabilitative Approach

Any treatment of LBP caused by vertebral deformity in adults must address two essential elements (see Table 33-8): degenerative instability and the reduction or loss of the physiological curvature of the lumbar segment in the sagittal plane. In fact, findings from various studies (387,393) have confirmed that there is no direct correlation between the degree of pain, the Cobb's angle of curvature, and the cause of scoliosis (degenerative, *de novo*, etc.). Schwab et al. (394), however, noted a statistically significant correlation between the angle of L3 and L4 in the frontal plane, the extent of lumbar lordosis measured from L1 to S1, and pain and disability. The discomfort felt by the patient increased with the widening of the spinal angle and the decrease in lumbar lordosis.

Scoliotic curves over 30 degrees Cobb at the end of skeletal maturity often evolve slowly and insidiously, involving both the anatomical structure of the curve and the functional status of the patient (376). This worsening seems to be a postural collapse that, at least initially, is not a real deformity because it is not structured. However, over time the permanent asymmetric

**FIGURE 33-14.** Improvement of balance and muscles stabilization function are two of the main points of adult scoliotic spine treatment.

load tends to modify the vertebral structure and can no longer be recovered. The development of curvature is accompanied in a linear way by an increase in CLBP and psychological suffering, and in the most serious cases by a reduction of cardiopulmonary function (395).

### Scoliosis Progression

Scoliosis is the most disabling deformity of the spine among adults (375). In addition to the concern for present disabilities, there is also the awareness that, as time passes, the condition will probably grow worse. Furthermore, when the major curve is at the lumbar and thoracolumbar levels, besides the worsening of rotation and lateral curvature there is the risk of a collapse into a disabling total round back and flexed anterior or lateral posture.

We find in the literature a growing amount of data confirming the possibility that exercise alone can in some cases slow down the development of scoliotic curvature, not only in the child but also in the adult (Fig. 33-14) (396). The reduction of scoliotic curvature certainly does not indicate a reduction of deformity but a recovery from the postural collapse, which is present in the upright posture. From a study by Torell and Nachemson, there is evidence that in adolescents, regardless of the magnitude of curvature, the mean difference between a standing radiography and a supine one is 9 degrees Cobb (397). There is no data in the literature to indicate precisely what this difference is (Duval-Beaupère called it “postural collapse”) (398) in adult scoliotic patients. Probably the recovery of this collapse is the key with which to avoid any worsening of adult curvature. On the other hand, the functional, cosmetic, and psychosocial damage caused by scoliosis is directly proportional to the magnitude of curvature (399) so an initial improvement, followed by stability over time, must be considered a remarkable success in the therapeutic treatment of AS.

The goals at the neuromotor and biomechanical levels are the recovery of postural collapse, postural control, and vertebral stability. The following are included as objectives of rehabilitative treatment:

- Becoming aware of pathology consequences and recovery possibilities for postural collapse

- Muscular strengthening and vertebral stabilization, always done in auto-correction, that is, in the position of maximum postural collapse recovery
- Global improvement of patient's function, even with a partial recovery of possible deficits in the joint range of motion and of muscular retractions, if present
- Development of balance
- Postural integration, which includes the neuromotor integration of correct postures and an ergonomic education program
- Functional improvement, with aerobic and respiratory exercises in the case of reduced cardiopulmonary function
- Cognitive behavioral approach, even in the absence of pain

### Back Pain and AS

The literature on spinal pain and scoliosis in adults is fairly uniform. In adult scoliotic subjects, researchers have found that the incidence of lumbar pain was similar to that of subjects without vertebral deviation (400), but the prevalence was higher (375,392,396,401). This pain seems to be more frequent in women after pregnancy or after a period of spinal mechanical overload (402), even if researchers have found no risk of debilitating LBP in adult patients whose lumbar scoliosis has not been treated. Moreover, there is a similar rate of surgery for lumbar pain in patients, either with or without scoliosis (403). Even if the symptom of pain is the main cause of surgical treatment requests for stabilization purposes, its extent cannot be correlated to the magnitude of curvature (404). Instead, there is a significant relationship between pain and the magnitude of lumbar lordosis. In fact, the increase of pain and reduction in quality of life are directly proportional to the flattening of the lumbar curve (394). For this reason, in the treatment of an adult patient with scoliosis and persistent lumbar pain, one of our goals is to recover/maintain sagittal curves with particular attention to the research of a good lumbar lordosis.

Strength-endurance training exercises that emphasize the extension of the spine can be particularly useful. In any case, the three-dimensional nature of scoliotic deviation requires that we pay attention to the starting position, which should be chosen after performing several tests to find the one most appropriate for the patient.

The scoliotic patient, like all subjects who report CLBP, also tends to develop a progressive fear-avoidance behavior, that is, a growing reduction of his/her activities for the sake of avoiding pain. In the acute phase this fear-avoidance behavior, as exemplified by rest, claudication or stick usage, has a protective effect against pain, given the reduced stress on the recovering structure.

Consequently, this behavior can persist in order to avoid pain, but it can also cause a progressive "disuse syndrome." Therefore, the treatment schedule for a patient who experiences CLBP must be organized from the cognitive behavioral perspective.

### Back Pain and Hyperkyphosis

Hyperkyphosis resulting from Scheuermann's disease, and from idiopathic or postural hyperkyphosis among adults, involve a pronounced rigidity of the thoracic section that leads to dysfunctional strain on the spinal segments retaining mobility, meaning the cervical spine and lumbar spine. While the mediadorsal spine benefits from a type of "natural" arthrodesis, which is just as efficient as surgery, the increased pressure on the transition areas of the lordotic curvatures above and below the thoracic kyphosis can cause localized stress and eventually lead the patient to experience cervical and LBP. Additionally, the apex of the kyphosis itself can at times become a locus of sharp pain that is difficult to manage. Rehabilitative measures should include exercises to control posture and recover function similar for those for nonspecific LBP.

## CONCLUSION

Today's approach to LBP requires deep knowledge of the actual evidence and the clinical specifics of the individual circumstance. A superficial, nonexpert approach to these problems is no longer acceptable. That is particularly the case in our specialty, because the evolution of knowledge in the literature, if not the expert consensus, indicates a PRM leadership role in the LBP field. In fact, excluding ALBP, a rehabilitative team approach eventually combined with PO treatments (but clearly distinguishing the two) is mandatory in most of the cases (21,22).

# Scoliosis and Other Spinal Deformities

## DEFINITION

One of the unique features that distinguishes humans from the animal kingdom is our bipedal nature. Quadrupedal ambulation is more stable, with built-in redundancies. However, by standing on our hind legs, we are able to see above many other vertebrates. Our arms and hands are freed to manipulate tools. The unique balance between flexibility and stability in the human spine helped to realize this evolutionary innovation. It is a wonder that this balance is maintained for a lifetime of wear and tear for the vast majority of the world's population. When that balance is altered, the result is deformity of the spine in one or more of its planes of movement. These conditions have likely been with man since bipedal mobility began. Hippocrates stated that "there are many variations of curvatures of the spine, even in persons who are in good health, for it takes place from natural conformations and from habit, and the spine is liable to be bent from old age and pains" (1).

We have advanced in the effectiveness of the treatment of spinal curvatures since the time of the ancient Greeks and Romans, when various types of traction devices and trunical wraps reportedly were advocated. However, Hippocrates' description of the pathophysiology of spinal curvatures is fairly accurate. In this chapter, we will discuss the evaluation and treatment of people disabled by spinal deformity, including those whom Hippocrates might have described as in good health (*idiopathic*), those with natural conformations (*congenital*), those with curves due to "habit" (*neuromuscular*), and those who are bent from old age and pains (*degenerative and traumatic*).

Colloquially, scoliosis is often used as a term to include all spinal deformities. The term was coined by Galen in the second century A.C.E (1). It is derived from the Greek word "skolios" (2), meaning bent, twisted, or curved. As such, it could include any spinal curvature. However, Galen defined it as the (abnormal) curve of the spine in the coronal (aka frontal) plane (Fig. 34-1). Sagittal plane pathology results from excess or reversal of the spine's natural sagittal curves. Kyphosis, the word Galen applied to sagittal curves with a posterior vertex (concave anteriorly), derives from the Greek word "kuphos" (2), meaning bent forward or humped. Within a range of degrees, it is normal in the thoracic spine. Lordosis is the word used to describe a sagittal curve with an anterior vertex (concave posteriorly). It derives from

"lordos" (2), meaning excessive posterior bending. Within a range of degrees, it is normal in the cervical and the lumbar spine (Fig. 34-2).

## WHAT IS A PATHOLOGICAL CURVE?

Although the presence of any fixed frontal curve could be considered outside of the design parameters of the spine and abnormal, it is generally accepted that some degree of frontal curve may be "within normal limits." The Scoliosis Research Society (SRS) has defined a medically significant frontal plane curve (scoliosis) as any curve which is greater or equal to 10 degrees, with or without a rotatory component (3). The definition of a pathological sagittal plane curve is less settled. The spine is "balanced" in the sagittal plane along a plumb line dropped from the center of C7 to the sacral promontory (4). This balance can be influenced by the position of the head and neck, as well as the pelvis and lower limbs. This dynamic balance may help explain some of the outstanding controversy about pathological sagittal curves. Numerous authors (1,5) give the normal range of thoracic kyphosis to be 20 to 40 degrees, others (1) give the range as 30 to 50 degrees. Fon et al. (6) have shown that kyphosis increases about 4 to 5 degrees over childhood to the end of adolescence. Kyphosis is also known to increase with aging. The SRS has agreed that normal thoracic kyphosis ranges from 20 to 50 degrees. The range of normal for lumbar lordosis is even wider. Jackson and McManus (7) found the mean lordosis to be 59 degrees. Vaz et al. (8) found a mean lumbar lordosis of 46.5 degrees, with a range from 26 to 76 degrees. The SRS has agreed (4) that normal lumbar lordosis can range from 31 to 79 degrees, depending on measurement technique. However, in assessing any curve detected in a clinical situation, it is important to neither simply rely on curve measurements which are within the "normal" range nor to consider the curve amplitude as the only factor in assessing the patient and his/her complaints and impairments.

## EPIDEMIOLOGY

As will be discussed later, spinal deformities can impair not only the musculoskeletal system but also many other organs and systems, often in people already coping with other impairments from chronic disabling conditions. Scoliosis

**FIGURE 34-1.** The planes of the body. (Courtesy of National Cancer Institute's SEER Program web-based training module.)

and the other spinal deformities are not uncommon. The prevalence of idiopathic scoliosis is reported to be between 0.3% and 2% of the population (9). The incidence of degenerative scoliosis is reported as 6% in people over 50 years of age and 36% in persons over 50 with osteoporosis (10). Scheuermann's disease, a common cause of pathological thoracic kyphosis, has a prevalence of between 0.4% and 8.3% of the population. Up to a 100% incidence of spinal deformity can be found in people with many neuromuscular conditions (see section on "Neuromuscular Scoliosis").

A physiatrist cannot avoid scoliosis by subspecializing. Spinal deformity is seen in all ages and almost every type of disabling condition (Table 34-1). Physiatrists who do not treat children cannot avoid childhood onset spinal deformities; they will encounter adults who had spinal deformities as children and need to help them address late sequelae of their deformities.

Hopefully, you have now gained an appreciation for the definition of scoliosis and its importance as an issue in the care of persons with disability and/or pain. We will now proceed to develop a construct to use to help better understand these conditions and effectively care for the persons with these disabilities

**FIGURE 34-2.** There are three basic types of pathological spinal curves. (Courtesy of Donald Bliss and Alan Hoofring of the Medical Arts and Publications Branch, NIH.)

TABLE 34.1 Types of Scoliosis and Typical Ages of Onset	
Pathophysiological Type of Scoliosis	Typical Age of Onset
Idiopathic	Infancy to adolescence
Neuromuscular	Childhood to adolescence
Bone or ligamentous dysfunction	Childhood
Traumatic/posttraumatic	All ages
Infectious or neoplastic	All ages
Degenerative	Middle age to seniors

and their families. By persevering through the remainder of this chapter, you will have the chance to

- Regain sufficient memory of the anatomy and physiology underlying the balance of the spine in order to appreciate the factors contributing to the various spinal deformity pathologies and to have a basis to develop a rational treatment plan
- Understand how to obtain the crucial historical, clinical, and radiographic data to form an educated diagnosis and prognosis
- Appreciate the impact of spinal deformity on a person’s quality of life
- Understand the pathophysiology and etiologies of spinal deformity
- Understand the roles of physiatric modalities in the (re) habilitation of persons with spinal deformity
- Understand the role of surgical treatment
- Consider the issues involved in postsurgical rehabilitation

## SPINAL ANATOMY AND PHYSIOLOGY

### Three Columns for the Price of One (Bony Functional Anatomy)

To achieve the elegant balance of flexibility and stability that the human spine offers, the design requires 7 cervical, 12 thoracic, 5 lumbar, and a fused set of sacral and vestigial coccygeal vertebrae. The stability comes from the fact that the spinal column is actually three columns in one. The anterior column is composed of the anterior longitudinal ligament and the anterior portion of the vertebral body. The middle column is made up of the posterior wall of the vertebral body and the posterior longitudinal ligament. The posterior column is formed by the posterior bony arch, which consists of the transverse processes, facets, laminae, and spinous processes. Each vertebra has the potential for six degrees of freedom (Fig. 34-3): translation in all three axes of movement and rotation around each axis. However, all vertebrae are not created equal. Movement at different levels of the spine is limited in some planes. In essence, in the function of the spine follows its form (with apologies to Louis Sullivan). The cervical vertebrae have the greatest

**FIGURE 34-3.** Six degrees of freedom are possible at each vertebra. The vertebra can move in each of the planes and rotate around each of the axes. (Courtesy of Donald Bliss and Alan Hoofring of the Medical Arts and Publications Branch, NIH.)

freedom including free flexion, extension, lateral rotation, and lateral flexion (this is fortunate, since this freedom affords the eyes and ears a wider field of function). This mobility is due to larger disks, concave lower and convex upper vertebral body surfaces, and transversely aligned facet joints. Thoracic vertebrae have restricted flexion and extension and limited rotation but freer lateral flexion due to their attachments to the rib cage, smaller disks, flatter vertebral body surfaces, frontally aligned facet joints, and overlapped spinous processes. The lumbar spine has good flexion and extension and free lateral flexion due to large disks, posteriorly directed spinous processes, and sagittally directed facet joints. However, there is only limited lateral lumbar rotation due to facet alignment (Fig. 34-4).

### Ties That Bind (Elastic Tissues)

The intervertebral disks form one fourth of the total length of the spinal column (11). Since they are a viscoelastic tissue, they serve as shock absorbers and take part of the load applied to the spinal column. They also redistribute the load applied on the vertebral bodies, moving more of the force to the stronger, cortical bone (arranged in parallel with the length of the spine) at the vertebral end plates than the thinner layer of cortex sandwiched between softer cancellous (and therefore weaker) bone in the center of the vertebral body. The disks also help connect the vertebra. And, as implied above, they participate in the articulation of the spine.

A number of ligaments also help to link the spine together. The anterior longitudinal ligament is a thick, strong ligament that stretches from the occiput to the sacrum along the anterior surface of the vertebral body. It attaches to the vertebral end plates and is confluent with the anterior portion of the annulus fibrosis of the disk. At the posterior aspect of

**FIGURE 34-4.** Typical vertebrae. (Courtesy of Donald Bliss and Alan Hoofring of the Medical Arts and Publications Branch, NIH.)

the vertebral body, there is a similar ligament, the posterior longitudinal ligament. However, it has an hourglass shape and is thinner than the anterior ligament. There are also three ligaments which connect portions of the posterior column of the spine. The supraspinous ligament stretches across the tips of the spinous processes while the interspinous ligaments stretch from one spinous process to the next. The ligamenta flava (flava is Latin for yellow and the ligament is that color due to the high proportion of elastic tissue within it) connect the laminae

of adjacent vertebrae from the anterior surface of the proximal lamina to the posterior surface of the distal lamina. They also blend in with the capsule of the zygapophyseal joints.

### Spinal Articulations

The spine has two primary joints. The intervertebral joints (as noted above) are formed by the surfaces of the vertebral bodies with the disks. These joints (with the restrictions noted above in the discussion of vertebral anatomy)

allow limited movement in all six directions, although each individual joint only moves to a small degree. The zygapophyseal joints are the only true synovial joints in the spine and are found at the junction of the pedicle with the lamina. The form of their alignment contributes significantly to the functional movement at different levels. The transverse alignment in the neck permits good flexibility in all planes. In the thoracic spine, the facets are aligned frontally which, along with the linkage to the rib cage, limits flexion and extension. The lumbar facets are arranged sagittally, limiting lateral rotation.

### Dynamic Balance

It would be possible to place a spine consisting of only its bony and elastic tissues on a base and have the spinal column *statically* balance in an upright position. However, if the point of the flexibility of the spine is to give humans the freedom to move on two legs, then the spine requires a complex system of dynamic control. The neuromuscular system provides this balance, actuated via muscles intrinsic and extrinsic to the spinal column. The paraspinal muscles are a series of layers of longitudinal muscles attached from the occiput to the sacrum. They are partially distinguishable by their fiber direction and length but “from a functional standpoint, there is little reason to subdivide the back musculature in any detail since the muscles work together in large groups” (11). They serve primarily as extensors to resist the pull of gravity in sitting and standing. In addition, the superficial layers will produce ipsilateral rotation when firing unilaterally, while the deeper groups will produce contralateral rotation with unilateral firing. The primary lateral flexors of the trunk are the quadrati lumborum and oblique abdominal muscles. The primary flexors are the psoas, assisted by the recti abdominus.

## CLINICAL ASSESSMENT OF THE PATIENTS WITH SPINAL DEFORMITY

### History

Like every other medical condition, most of the diagnosis can be made just by taking a good clinical, functional history and performing a physical examination. “As each symptom is given, it should be pursued with a dogged tenacity until all the details are known” (12). We have mentioned that the majority of patients with scoliosis have an idiopathic condition. It is critical to first rule out spinal deformity associated with another disabling condition. Much of this will be accomplished with good history taking which can then direct and focus the physical and radiological examinations.

The first clue to the etiology of the deformity will be the age of onset. If the scoliosis presents at or soon after birth, it is more likely to be associated with a congenital bony deformity or inherited disease involving the neuromuscular system. If the scoliosis begins in late childhood or adolescence, it is likely to be idiopathic. Spinal deformity that begins in young adulthood is most likely due to trauma or infection; in middle age

or later, it is likely to be associated with degenerative disk or joint disease and/or osteoporosis.

It is also important to determine if the onset of the curve is associated with any acute problem such as trauma or infection. The degree of curvature and how fast the size of the curve increases also offer insights into etiology. An underlying neuromuscular or ligamentous condition may promote quicker progression. Children within their adolescent growth spurt may have greater progression due to the rate of overall growth. Progression in an older adult may be an indicator of poor bone health.

Details relating to the nature of the curve itself are insufficient to advance the development of a good diagnosis and rational treatment plan. It is vital to inquire about associated complaints, signs, and symptoms. A thorough review of systems should be performed. However, certain areas of inquiry are more likely to yield clues. Although pain is associated with spinal deformity in adults, it is uncommon in children and adolescents (13) and obligates the physiatrist to search for underlying pathologies including neoplasm or infection. Similar to other pain-evoking conditions, details about the quality, intensity, and temporal and spatial parameters of the pain will help distinguish among bony, soft-tissue-based, and neuromuscular-based pain. Cardiopulmonary dysfunction is the most serious morbidity of spinal deformity. Therefore, questions about fatigability, shortness of breath, palpitations, and decrease in endurance must be included in the history. Any suggestion of cardiopulmonary dysfunction should lead to a more rapid and aggressive workup.

It is important to inquire about the symptoms of central nervous system dysfunction. Problems with loss of balance or falls may indicate a coordination problem such as is seen in cerebellar syndromes. Complaints of muscle spasms may indicate spasticity. Conversely, complaints of weakness or sensory loss may indicate peripheral nervous and/or muscle pathology. Reports of frequent joint sprains may indicate the presence of a condition associated with ligamentous laxity. In children and adolescents, it is important to obtain a history of developmental milestones. Indication of delay in any of the developmental spheres—social/behavioral, communication and cognition, fine motor, gross motor—may provide clues to the presence of an underlying syndrome. Since spinal deformity may be initiated or exacerbated by conditions affecting other areas of the body, the physiatrist should ask about conditions that may affect the lower limbs, such as a history of hip dislocation or leg length discrepancy, and even conditions associated with asymmetry of the upper limbs and head.

Last, but certainly not least, a thorough social and functional history must be obtained. Further clues into etiology may be gleaned. In addition, the insights obtained will identify the barriers to successful functional outcome to the treatment plan and ensure that the goals of the rehabilitation team are in concert with the goals of the patient and his or her family. In some cases, it may be beneficial to use a standardized questionnaire to follow the impact of the person's spinal deformity on the function and related aspects of quality of life. There

is a validated instrument focused specifically on persons with spinal deformity (14–16). Alternatively, one of the many generic “disability/burden of care” or “health-related quality of life” instruments may be used (see Chapters 11 and 18).

### Physiatric Clinical Examination

Although school screening programs for idiopathic scoliosis may only look at a child’s spine, it is not sufficient for a physiatrist to limit the assessment of spinal deformity to the spine. A comprehensive physiatric examination must first be done. This should include assessment of pain, strength, endurance, sensation, balance (in sitting and standing), coordination, range of motion, reflexes, mobility, and dressing skills. Leg length discrepancy should be assessed, which is not always easy to determine, and corrected.

Once the general examination has been completed, a more focused assessment of the spine must be performed. You do not have Superman’s x-ray vision; clothing must be removed so that the spine can be observed directly. The surface anatomy should be viewed in both prone and side lying. If the patient can sit, then the spine must be seen in sitting. If he or she can stand, even with support, then the spine must be viewed in standing. If there is concern about leg length discrepancy and/or pelvic asymmetry, the spine should also be viewed in standing with leveling blocks under the foot on the “short” side and the depth

of the correction recorded. Any difference in the shape or degree of curve in different positions should be noted, it is a sign of the degree of flexibility of the curve. The spine should be viewed from both the frontal and sagittal planes. The spinous processes should be palpated to better appreciate the curves’ dimensions, including shape in both frontal and sagittal planes and presence of rotation. The curve should be described by its length (approximately which vertebrae start and end the curve), its shape (e.g., “C” or “S” shaped), and the direction of the vertex of the curve. Truncal range of motion in all planes—forward flexion, rearward extension, R & L lateral flexion, and R & L lateral rotation—should be viewed with special attention to asymmetry and spinal levels where movement is occurring. While the patient is flexing forward, the examiner should look at the shape of the rib cage for prominence or humping (Adam’s forward bending test (17), which is the test used in school screenings) (Fig. 34-5), which may be a sign of a rotatory component to the curve. The shape of the rib cage should be viewed from all angles to look for deformity. Rib cage deformity may not only be a sign of rotation of the vertebrae but also suggest underlying pathologies such as osteogenesis imperfecta. One must look not only at rib prominence but also for deformities such as pectus carinatum or excavatum. Symmetry at the top and bottom of the trunk should be assessed in sitting and standing. Shoulder

**FIGURE 34-5.** Adam’s forward bending test. (Courtesy of Donald Bliss and Alan Hoofring of the Medical Arts and Publications Branch, NIH.)

symmetry should be viewed at the level of the acromioclavicular joint (13). Pelvic symmetry can be viewed either at the brim of the pelvis at the iliac crests or at the posterior superior iliac spines, which is seen on the surface of the buttocks as the two sacral “dimples.”

Measurement of symmetry of the appendicular skeleton and head should be done to rule out asymmetries. Head size and alignment should be viewed since reports have associated these issues with scoliosis (18). There are reported associations between upper limb deficiency and scoliosis (19–21), and, anecdotally, it has been associated with neonatal brachio-plexopathy (Erb’s palsy). Therefore, upper limb asymmetries should be assessed. Upper limb length should be measured in a consistent manner. One method is to measure from the acromioclavicular joint to the radial styloid. Lower limb discrepancy produces functional scoliosis in standing and it may contribute to the development of fixed scoliosis, as well (22). Lower limb length is commonly measured from the anterior superior iliac spine at the pelvis down to the medial malleolus. The physiatrist must also look for functional asymmetries that could result from joint contractures or deformities (especially at the hips and knees) or tendon contractures (especially tendons of two joint muscles such as the hamstrings and gastrocnemius). Functional asymmetry may also result from asymmetric neurological function including hemiparesis.

## RADIOGRAPHIC ASSESSMENT OF THE SPINE

### Measuring the Curve Angle

The standard technique for measuring the angle of a spinal curve is called the Cobb angle (23). Initially developed as a frontal plane measurement, the technique can also be used for assessing sagittal curves. We will review the method for assessing scoliosis, but the rules can be applied similarly in lordosis and kyphosis. The film from which the curve is viewed should, if possible, include the entire spine on one film and be taken posterior-anterior (to reduce the dose of radiation to the breast) (13). Even if the patient is only suspected of having a frontal curve, a lateral film must also be obtained to better assess the amount of rotation in the curve. If at all possible, the films should be done in standing. If the patient is unable to stand, then sitting is preferred to a supine film. The P-A film should be taken with the arms at the side; the lateral film should be done with the arms at 90 degrees of abduction to keep the upper limb from obscuring the spine. Although it is common to shield the perineum when films are done, the initial films should be done without gonadal shield in order to fully visualize the hips, pelvis, and proximal femurs (13). In children and adolescents, a sense of skeletal maturity can be gleaned by looking for Risser’s lines at the crest of the pelvis.

To perform the Cobb measurement, the examiner should first note the upper border, lower border, and vertex of the curve. The curve is classified by the position of the vertex into thoracic, thoracolumbar (vertex at the thoracolumbar junction), or lumbar. The upper and lower borders are

identified by the “end vertebrae.” They are the first and last vertebrae that tilt into the concavity of the curve (13). To define the angle, a line is drawn on the radiograph parallel to the upper end plate of the upper end vertebra. A second angle is drawn parallel to the lower end plate of the lower end vertebra. In most cases, these lines will not intersect on the film and, therefore, the angle cannot be measured directly. Instead, using principles learned in high school geometry, a line perpendicular (90 degree angle) to each of the above lines is drawn. The angle formed by the intersection of the perpendicular lines is equal to the angle made by the upper and lower end vertebrae and is measured and reported as the Cobb angle (Fig. 34-6).

More and more facilities are converting to filmless, computer-based radiological information systems. Many of these systems offer tools to directly measure the Cobb angle on the screen. The semimanual methods still require the clinician to place the parallel lines at the top and bottom of the curves. Studies have shown these methods to have precision and

**FIGURE 34-6.** Measuring the Cobb angle. (Courtesy of Donald Bliss and Alan Hoofring of the Medical Arts and Publications Branch, NIH.)

reliability similar to the film-based method (24–26). More recently, some systems have introduced fully automated Cobb angle calculations. However, it appears that this technology still requires further refinement to achieve adequate accuracy for curves of all magnitudes (27).

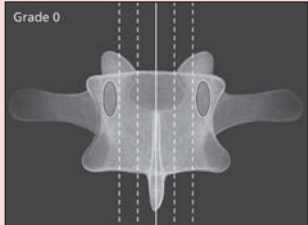

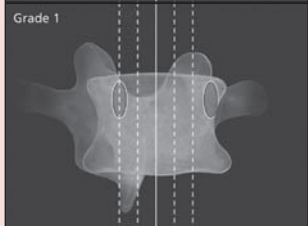

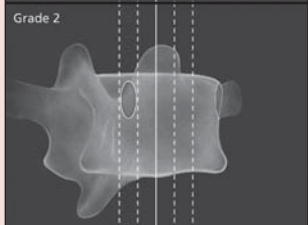

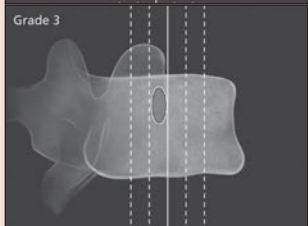

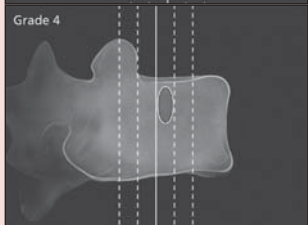

### Assessing Rotation

As mentioned above, the spine has six degrees of freedom, including rotation along the axis of the spinal cord. Many spinal curves are associated with rotation of the vertebrae. Curves with rotation may be more difficult to treat and may cause greater disturbance to the rib cage with resultant adverse effects on respiration. Therefore, it is important to assess the presence and degree of rotation associated with the curve, as well as its rate of

progression. Radiographically, the position of the pedicles provides the best sense of degree of rotation on a plain x-ray. The examiner should note the symmetry and alignment of the pedicles in the P-A film. If asymmetry is present, the pedicle that is more prominent will indicate rotation away from that side of the vertebra. The degree of rotation can be graded using the system of Nash and Moe (13) (Table 34-2). Automated computerized systems to assess rotation are also under development (28).

New computer-assisted techniques are also under development to supply additional information about the three-dimensional characteristics of the curve using the data supplied by digitized plain films (29). Such information may be useful in assessing the results of nonoperative and for planning operative treatments. Despite the additional radiation dosage,

**TABLE 34.2 Moe-Nash Classification of Spinal Rotation**

Nash and Moe Grade	Description	Figure
Grade 0	Pedicles are seen symmetrically positioned at the lateral border of the vertebral bodies	
Grade I	Slight asymmetry	
Grade II	One pedicle is almost out of view	
Grade III	Only one pedicle is seen, positioned at the center of the vertebral body	
Grade IV	Only one pedicle is seen, positioned lateral to the center of the vertebral body	

three-dimensional CT may be useful, especially in congenital disorders (30,31). MRI might offer similar information without radiation exposure (although still with the need for sedation in groups including young children and adults with claustrophobia); however, at the current state of technology, recommendations for its use are still limited to ruling out potential etiologies or neurological abnormalities (32). It is also important to remember that neither CT nor MRI is able to assess the impact of gravity on a curve, since both studies are done in a supine position.

### Assessing Vertebral Integrity

It should be obvious by now that among the etiologies of spinal curves are conditions intrinsic to the bone. Most of these will become evident upon careful inspection of the radiographs obtained to determine the magnitude of curvature. The spinal elements should be inspected for signs of hemivertebra, unsegmented bars, and/or bifid spinous processes (see Fig. 34-10 later in this chapter). The ribs should be viewed to look for asymmetry or changes in the natural curve (Fig. 34-7). The pelvis should be examined for signs of asymmetry (Fig. 34-8). The hip joint should be examined for signs of subluxation. Femurs should be assessed for any asymmetry and separate femur films ordered if there is any suspicion of pathology.

## THE IMPACT OF SCOLIOSIS ON LIFE FUNCTION (SECONDARY MORBIDITIES)

The reason that this chapter is found in *Physical Medicine and Rehabilitation: Principles and Practice* is because spinal deformity is not just a cosmetic problem; it impacts on many aspects of quality of life. The types of functional morbidities and their intensity may vary with curves of different etiologies; however, certain problems may be found in almost all types of spinal deformity. In this section, we will review the areas of most common functional concern in persons with spinal curves.

### Pain

Pain may be the presenting symptom of spinal deformity; it is in 40% to 90% of adult scoliosis (33). In thoracic kyphosis caused by Scheuermann's disease, it is an early symptom in 20% to 60% of patients. However, before attributing pain to idiopathic or degenerative etiologies, it is vital to remember that pain may be the sentinel of a critical, even fatal illness. Pain may be the presenting symptom in infectious processes such as epidural abscess or discitis (34). Rarely, one can have a spontaneous epidural hematoma of the spine. In these cases, due to nerve irritation, the pain may be radicular in character. Of greatest concern is to rule out pain due to tumor. In benign

tumors, the delay between the onset of symptoms and the diagnosis can be up to 19 months. In malignant tumors, it can be up to 4 months between symptom onset and diagnosis. It is important to recall that tumor-related pain is often worse at night and is disassociated from any obvious initiating or exacerbating factors (35).

Chronic pain plays a role in many spinal curvature pathologies. As implied above, it is common in degenerative spine conditions with associated curvature. More than 50% of patients with Scheuermann's disease have pain later in their course, especially if  $L_1$  and  $L_2$  are involved (36). There appears to be an increased risk of pain in adults who had scoliosis in childhood or adolescence (37). Pain is often a problem in persons with achondroplasia and is felt to be associated with the mechanical disadvantage of the lordosis on sagittal spinal alignment. Back pain is also found in osteogenesis imperfecta. The pain in osteogenesis imperfecta may also be related to the mechanical disadvantage of the lordosis.

### Mobility

As noted above, normal spine function is a delicate dynamic balance between rigidity and flexibility. It is not surprising, then, that balance may be affected by spinal deformity. When the patient has an underlying neuromuscular condition, the spine asymmetry is likely to exacerbate the difficulties with balance control. What is more unanticipated is that balance is disturbed in idiopathic scoliosis as well. Reports have shown increased amounts of sagittal and lateral sway in standing, along with increased sway radius, leading to decreased stability in standing (38). This may result in increased losses of balance and falls as well as increased and asymmetric stress on lower limb joints, creating the potential for a vicious cycle. Recent reports suggest that there may be subtle underlying neurological deficits in persons with idiopathic scoliosis manifesting as balance difficulties (39,40).

### Cardiopulmonary Function

The most critical of all of the potential complications associated with spinal deformity is compromise to the cardiopulmonary system. There is a common pathway toward cardiopulmonary dysfunction. It begins with restrictive lung disease resulting from deformity of the bellows mechanism formed by the rib cage, thoracic spine, and diaphragm. On pulmonary function testing, this is demonstrated by greater decreases in vital capacity than residual lung volume (41). In untreated idiopathic scoliosis, it has been shown that once curves achieve an angle of 70 degrees there will be a mild decrease in vital capacity. By the time a curve reaches 90 to 100 degrees, the patient will have dyspnea on effort. With curves greater than 100 degrees, alveolar hyperventilation,  $CO_2$  retention, pulmonary hypertension, and right-sided heart failure are seen (37,41). At this point, the patient may be irrevocably set on a downward slide of illness leading to death due to pneumonia and/or heart failure. It is likely that these problems will present with much smaller curves when there is also an underlying neuromuscular disease or syndrome affecting other organ systems.

Prevention of serious cardiopulmonary decline is one of the major indications for surgical correction. Close monitoring of pulmonary function tests is an essential part of ongoing follow-up of any patient with spinal deformity, especially if progression is noted. It is quite important to remember that there is a "window of opportunity" in progressive curves and that surgery in such curves must be done before pulmonary function has deteriorated to such a degree that the risk of inability to wean from mechanical ventilation after surgery is greater than the potential benefits of the surgery.

### Emotional and Behavioral Health

A physiatrist is obligated to approach his/her patient holistically. As with any other disability, the emotional impact of spinal deformity should be addressed. Spinal deformity has traditionally had tragic, negative connotations in Western society as evidenced by Shakespeare's Richard III and Victor Hugo's *Quasimodo, The Hunchback of Notre Dame*. Our modern society often appears obsessed with physical beauty and it seems as if these societal pressures are greater on women and girls. It is important, then, to be mindful of the potential impact that spinal deformity may play on the patient's body image and emotional health. Studies of patients with idiopathic scoliosis bear out this concern, with findings showing poorer body image, greater unhappiness, lower self-esteem, increased participation in high-risk behaviors, and greater incidence of depression (42–44). Questions relating to the emotional and behavioral status of a patient with spinal deformity should be a regular part of the physiatrist's ongoing follow-up of the patient. There should be no hesitation to enlist the help of psychological support professionals such as rehabilitation psychologists and social workers to address the emotional needs of the patients and their families.

### PATHOPHYSIOLOGY OF SCOLIOSIS

Spinal stability is derived from the design of the bony, elastic, and muscular elements of the spine and how they are controlled by the nervous system. The bony anatomy has a fair degree of intrinsic stability engineered into it, but must allow movement. Stability is reinforced by the elastic structures but, by their very nature, they will allow movement. The motor control system is designed to adjust to the movements engineered into the bone and elastic tissue system. Understanding the anatomy enables one to determine factors contributing to spinal curvature and better formulate a plan of treatment.

One useful division is to separate factors intrinsic to the spinal column from extrinsic factors. In looking at the intrinsic factors, one should consider how aspects of each of the elements of the spine—bony, elastic, and neuromuscular—may be affected. Once one has identified which systems are involved, the type of involvement should be understood. Is there a failure in the system or is the system overactive? Then, consider the etiology of the impairment. Is it congenital or

**FIGURE 34-9.** Pathological factors contributing to spinal deformities. (Courtesy of Donald Bliss and Alan Hooft of the Medical Arts and Publications Branch, NIH.)

acquired? If it is acquired, is the etiology traumatic, infectious, neoplastic, autoimmune, or degenerative? Understanding the biology of the dysfunction is important, that is, is the problem due to a metabolic defect in the tissue or is the tissue reacting to an outside influence. The nature of how these systems interact should also be considered. For example, does the elastic pathology cause secondary bony deformity?

Factors extrinsic to the spine can influence the spine in one of two ways. They can directly impact on the mechanical function of the spine by applying asymmetric forces to the bony and elastic tissue complex of the spine. Disorders resulting in misalignment of the appendicular skeleton, rib cage, and/or head can also apply abnormal forces to the spine. The spine can also be indirectly influenced by abnormal, especially asymmetric, function of the neuromuscular system extrinsic to the spine itself, even if spinal neuromuscular system is intact. It should also be remembered that this extrinsic neuromuscular dysfunction can directly affect the spine or it can indirectly influence the spine by causing extrinsic mechanical failures such as joint contractures or dislocations.

Figure 34-9 is a graphical representation of how all these factors may be organized. However, the relationship between the all of the factors—intrinsic and extrinsic—is even more complex than it appears because of the potential for interactions between each and every factor. Table 34-3 is a list of pathological conditions associated with spinal deformity grouped by category, based on the taxonomy developed by the SRS (9).

## SCOLIOSIS DUE TO BONY DYSFUNCTION

### Congenital

A number of disorders of vertebral development can occur. These anomalies are present at birth, but they may not be detected

immediately. The curvature may be subtle and not noticed until the child begins sitting or standing. Often, clinical evidence of curvature may not be apparent until the child grows and one part of the vertebral column grows faster than another, thus revealing the asymmetry associated with the anomaly. Winter (45) has developed a classification system for these anomalies based on the underlying embryological dysfunction. The dysfunction may be a failure of segmentation, a failure of formation, or a combination of both. The archetype of segmentation failure is a bloc vertebra, formed at two or more spinal levels. This is less likely to cause a curve than a unilateral failure to segment, known as a unilateral bar. The location of the bar will determine the type of pathological curve. A lateral bar will result in scoliosis, a posterior bar will produce kyphosis, and an anterior bar will result in lordosis.

The defect in formation that will result in curvature is usually called a hemivertebra. In reality, any amount of partial defect is possible. The partial vertebra may be “incarcerated,” meaning that the vertebrae above and below it have altered their shape to compensate for the abnormal shape of the partial vertebra, therefore limiting the degree of curvature. A nonincarcerated hemivertebra is more likely to result in curvature because its neighboring vertebrae have not adapted to the hemivertebra’s abnormal shape. Figure 34-10 shows representations of the basic types of deformities according to the Winter classification.

Although congenital bony anomalies may be isolated, it is incumbent to first rule out associated genetic disorders. From 25% to 40% of children with congenital bony anomalies also have other problems including genitourinary anomalies, cardiac anomalies, Klippel-Feil syndrome, and spondylothoracic dysplasia. However, the majority of curves due to congenital bony anomalies are not severe. Only 38% show severe progression, whereas 47% show only mild to moderate

**TABLE 34.3 Classification of Scoliosis Based on the SRS Taxonomy**

Idiopathic	Limb-girdle	Soft-tissue contractures
Infantile (0–3 y old)	Facioscapulohumeral	Post empyema
Resolving	Congenital hypotonia	Burns
Progressive	Myotonic dystrophy	Other
Juvenile (4 y—puberty onset)	Other	Osteochondrodystrophies
Adolescent (puberty onset—epiphyseal closure)	Congenital	Achondroplasia
Adult (after epiphyseal closure)	Congenital scoliosis	Spondyloepiphyseal dysplasia
Neuromuscular	Failure of formation	Diastrophic dwarfism
Neuropathic	Wedge vertebra	Mucopolysaccharidoses
Upper motor neuron lesion	Hemivertebra	Other
Cerebral palsy	Failure of segmentation	Tumor
Spinocerebellar degeneration	Unilateral bar	Benign
Friedreich's	Bilateral bar ("fusion")	Malignant
Roussy-Levy	Mixed	Rheumatic diseases
Spinocerebellar (olivopontine) ataxia	Associated with neural tube defects	Metabolic
Syringomyelia	Myelomeningocele	Rickets
Spinal cord trauma or tumor	Meningocele	Juvenile osteoporosis
Other	Spinal dysraphism	Related to lumbosacral dysfunction
Lower motor neuron lesion	Other	Spondylolysis
Poliomyelitis	Neurofibromatosis	Spondylolisthesis
Spinal muscular atrophy	Mesenchymal tissue disease	Other
Amyotrophic lateral sclerosis	Marfan	Thoracogenic
Charcot-Marie-Tooth	Homocystinuria	Postthoracoplasty
Myelomeningocele	Ehlers-Danlos	Postthoracotomy
Dysautonomia (Riley-Day)	Osteogenesis imperfecta	Other
Other	Other	Hysterical
Myopathic	Traumatic	Functional
Arthrogryposis	Fracture and/or dislocation without paralysis	Postural
Muscular dystrophy	Post radiation therapy	Due to leg length discrepancy
Duchenne	Other	Due to muscle spasm
		Other

progression and 15% show no progression (46). The character of the curve will help determine likelihood of success of a given treatment approach. Long, flexible curves may respond to orthotic management. Short, stiff curves will require surgery if they progress.

### Acquired Bony Pathology

The bony spine can be directly injured by blunt force or projectile trauma (see Chapter 27). This trauma can result in fracture and/or dislocation of spinal elements. Each year, there are between 18,000 and 50,000 spine fractures in the United States (47,48). The spine can also be injured as an unintended side effect of radiation. The instability resulting from spinal trauma can result in pathological spinal curvature, even without injury to the spinal cord. Development of pathological curvature is more common when the patient is managed without surgery, but curves can also occur after surgery, often as a result of non-union of fusion and/or implant failure. Kyphosis is the most commonly seen deformity after spinal trauma. When surgery is indicated, this may require both posterior and anterior fusion (48).

Historically, tuberculosis was a common cause of spinal deformity. TB osteomyelitis, known as Pott's disease, has been found in Egyptian mummies (49). Most often, it produces a sharply localized kyphosis called a gibbus deformity. TB is still important to consider, especially due to the prevalence of atypical forms of mycobacteria in immunocompromised populations such as persons with HIV. Acute pyogenic osteomyelitis, most likely due to *Staphylococcus aureus*, is more common than TB. It will present with associated fever, malaise, and back pain. There will be elevations in white blood cell count and ESR. Unfortunately, plain x-rays may not reveal any pathology for 10 to 14 days after the onset of symptoms. Damage usually starts in the vertebral body and spreads via the disk to other levels. It is uncommon for the infection to start in the disk or posterior spinal elements. As in TB, kyphotic deformity is most common (49). Treatment for these deformities depends on the number of levels involved. A one-level infection may be managed with a spinal orthosis. If two or more levels are involved, surgical intervention will likely be needed; neurosurgical participation will often be required to prevent spinal cord compromise (49).

**FIGURE 34-10.** Basic types of anomalies in congenital scoliosis (based on Winter classification). (Courtesy of Donald Bliss and Alan Hoofring of the Medical Arts and Publications Branch, NIH.)

Although less than 10% of all neoplasms are primary bone tumors, 50% to 70% of persons who have died of neoplastic disease have shown some evidence of bony involvement (35). The spine is the most common site of bone metastases (35), making neoplasm an important potential etiology of spinal deformity. Pain will often be the first symptom. In adults, malignant tumors are more often found in the vertebral body or pedicle, whereas benign tumors are found more often in the posterior elements. Primary benign tumors include osteoid osteoma, osteblastoma, giant cell tumor, and aneurismal bone cyst (which is not a true tumor but rather a hyperemic osteolytic process) (35). Osteoid osteoma usually resolves after surgical removal, which should limit deformity. Osteblastoma, although rare (<1% of all primary bone tumors), is present in the spine in 40% of cases. Half of those cases will have scoliosis (35). Aneurysmal bone cysts may involve the neural arch, body or posterior elements and can produce scoliosis or kyphosis due to osteolysis. While only 12% of giant cell tumors involve the spine, 50% of those that do will involve the vertebral body and can result in vertebral body collapse and subsequent kyphosis and/or scoliosis (35).

Primary malignant bone tumors are rare and do not commonly involve the spine. Less than 2% of osteosarcoma, only about 5% of Ewing's sarcoma, and not many more of chondrosarcomas are found in the spine. If they are successfully removed before the spine becomes unstable, spinal deformity is unlikely (35). However, as noted above, metastases to the spine are common in solid tumors including those originating in the breast, prostate, thyroid, kidney, bronchus, esophagus, the gastrointestinal tract, and the rectum. Of white blood

cell-derived tumors, multiple myeloma is most commonly found in the spine, although lymphoma is also found. As with other spinal neoplasms, metastases usually present with pain. If pathological spinal curvature is present in metastatic bone disease, it is quite possible that the tumor has caused spine instability and urgent evaluation and treatment should be performed to prevent neurological compromise.

The most common cause of acquired spinal deformity arising from the bony spine is degenerative. The overall incidence of degenerative spinal curvature is between 2% and 4% of the population (50). Since the presenting problem is usually pain, it is important to first rule out underlying pathologies. Temporary, functional curvature can result from neurogenic pain or disk or facet pathology (51) and should be distinguished from fixed curve. Spinal deformity is fairly common in women with osteoporosis, with scoliosis occurring in between 36% and 48% (52). The onset of curvature is thought to occur in the 5th decade of life, but it is possible that subtle changes occur earlier but are clinically undetectable (52). Primary adult spinal deformity is due to asymmetric vertebral collapse (51). There is a positive correlation between osteoporosis and the presence of thoracic kyphosis (5). However, the role of osteoporosis in frontal plane deformity is still controversial (51). Most biomechanists believe that degeneration of the intervertebral disks plays an important role. The loss of disk height and its ability to more evenly distribute force across the vertebral body is felt to increase the stress and load on the vertebral bodies, thus promoting collapse (53). Osteoarthritis and lax elastic tissues can result in abnormal spinal motion with resultant abnormal

stresses and this may also play a role (54). The most common primary curves are thoracic kyphosis and lumbar scoliosis. The scoliotic curves are usually short and focused at L2-3 or L3-4. They are detected by the 6th decade of life and are associated with a loss of lumbar lordosis. To better plan treatment, it is important to rule out curves which may have resulted from secondary degeneration caused by other bony pathology within and without the spine. This includes congenital anomalies such as facet asymmetry, idiopathic childhood or adolescent scoliosis, deformity resulting from trauma, infection, neoplasm, or autoimmune disease (e.g., kyphosis due to ankylosing spondylitis (50)), unilateral spondylosis, and extraspinal asymmetries such as leg length discrepancy (51).

## SCOLIOSIS DUE TO ELASTIC TISSUE DYSFUNCTION

### Congenital

Many inherited disorders of connective tissues are associated with spinal deformity. They include diseases such as osteogenesis imperfecta, achondroplasia, Marfan syndrome, and Ehlers-Danlos syndrome. OI and achondroplasia are examples of complex conditions that impact on both bone and connective tissue. Along with the knowledge of unique aspects of each disease, the physiatrist should be able to apply his/her understanding of how “pure” bone and “pure” elastic tissue syndromes impact on spinal curvature. As such, we will focus this section on Marfan and Ehlers-Danlos syndromes as examples of conditions that more “purely” affect elastic tissues.

Marfan syndrome (listed in Online Mendelian Inheritance in Man as OMIM #154700) is an autosomal dominant syndrome that results from a defect in the fibrillin gene at chromosome 15q21.1 (55). In addition to diffuse joint laxity (including the spine) and long limbs, it produces ocular deficits including myopia and flat corneas, and valvular heart dysfunction including mitral valve prolapse, aortic valve regurgitation, and dilation of the aortic root (which can lead to potentially fatal aortic aneurysm). Scoliosis may be seen in 52% of Marfan patients (56). When present, the curves tend to be severe and double major curves (i.e., “S” curve with thoracic and lumbar components) are common (57). In addition to the prevalence of long limbs, one study has shown a 5% prevalence of leg length discrepancy greater than 2 cm in Marfan patients. In that group with leg length discrepancy, over 90% had scoliosis greater than 10 degrees (56). This suggests that the pathology of spinal curvature in Marfan syndrome is not only due to the diffuse joint laxity. Since these patients are at risk for severe curves, they should be followed closely. Bracing should be begun at the lower end of the range of curvature treatment. If the curve progresses despite bracing, decision to proceed to surgery should also be done at the lower end of the treatment range.

Ehlers-Danlos is a family of genetic disorders (types I to VIII are OMIM #13000, 130010, 130020, 130050, 225400, 130060, 130080; there are more associated conditions) phenotypically associated with diffuse joint laxity (58–65). Types VI

and VII have most often been associated with kyphoscoliosis (58–65). Types VI and VII have most often been associated with kyphoscoliosis (63,64). The actual incidence of spinal curvature in these groups is not yet well-known (66). Type VI is an autosomal recessive disorder presenting with joint laxity and recurrent joint subluxations, Marfanoid habitus, risk of ocular rupture and a progressive, often neonatal onset, scoliosis. Decreased hydroxylysine is found on laboratory investigation and many of the cases have a deficiency in the enzyme lysyl hydroxylase (63). Double major curve appears to be the predominant pattern of scoliosis in this group (67). Type VII is an autosomal dominant disorder which results from defects in the COL1A1 and COL1A2 genes (which happen to also be involved in osteogenesis imperfecta). This type of EDS is associated with severely lax joints and frequently recurrent subluxations. They also have short stature and midface hypoplasia. Hypotonia and gross motor delay are also commonly seen. Kyphoscoliosis is the most common curve pattern in this group (64). Scoliosis is also reported in up to 50% of persons with one of the more benign types of Ehlers-Danlos, EDS III (67). Persons with EDS have vascular fragility often resulting in easy bruising. This aspect of EDS must be carefully considered in planning treatment of the curvature. Type of brace chosen and fit is thus more crucial than in other disorders. Surgery has the potential for increased blood loss, perioperative arterial rupture, wound hematoma, and wound dehiscence due to the fragile blood vessels (66,67).

### Acquired

It is difficult to identify acquired conditions which purely affect the elastic tissues without affecting the bony spine. Trauma, infection, and neoplasm do not often limit themselves to only the elastic spinal column tissues. Rheumatologic “connective tissue diseases” also do not limit their damage to elastic tissues. However, as noted above in the discussion of degenerative spinal disorders, disk disease is considered to be a major contributor to bony degeneration. Additionally, there are some conditions where it is important to be mindful of the possibility of spinal deformity due to soft-tissue contractures. They include emphysema with resultant lung and pleural scarring (68), contractures, due to burns or other injuries, and radiation fibrosis (9).

## SCOLIOSIS DUE TO NEUROMUSCULAR DYSFUNCTION

### Congenital

Scoliosis in inherited neuromuscular conditions can derive from three basic etiological categories: peripheral weakness, abnormal central control, and abnormal sensory afferent input. Weakness can cause failure of the dynamic balance of the spine and result in curvature. This occurs in lower motor neuron disorders such as spinal muscular atrophy and Charcot-Marie-Tooth disease (which also has a sensory component). It is also a factor in meningocele, whose pathology is more complex, since it is also associated with bony deformities. Weakness is also the etiology in curves resulting from

myopathic conditions such as the muscular dystrophies, congenital hypotonia, and myotonic dystrophy. Abnormal central control of dynamic spinal balance occurs in conditions including cerebral palsy and the spinocerebellar disorders (although some of them, such as Friedreich's ataxia, are more complex, with additional pathologies such as peripheral nervous system-derived loss of sensation). Riley-Day familial dysautonomia (an autosomal recessive disorder at chromosome 9q31-q33, which primarily affects Ashkenazi Jews) is a good example of a condition with scoliosis due to loss of sensation on the basis of dysfunction in peripheral afferent nerves (69).

All of the curves associated with congenital neuromuscular conditions have some common features. These include similar temporal characteristics: early onset, rapid progression during childhood and/or adolescent growth spurts, and curve progression, which continues into adulthood, since the underlying pathology is still present (70). They often also have an association with dependence in sitting with asymmetric trunk and/or pelvic obliquity (71). However, the pattern of the scoliosis may be similar to that seen in idiopathic scoliosis (72). The inevitability of progression in the more severe types of these disorders means that pulmonary compromise will eventually appear if the curve goes untreated. As mentioned in the section discussing the impact of curves on life function, this is the most serious of all curve-related complications. It is further complicated by the association with cardiac complications that many neuromuscular conditions have, including Duchenne muscular dystrophy and Friedreich's ataxia (70). These factors preclude any hesitation to proceed to earlier surgical management in order to slow respiratory compromise. There appears to be only a limited role for bracing in neuromuscular patients. It appears to only be effective in preventing progression in patients who are still ambulatory, but it can also be used as a sitting support and/or comfort measure (73).

Spinal muscular atrophy is a large group of disorders that affect the motor neurons in the anterior horn of the spinal cord, resulting in progressive weakness. The prevalence of curvature is reported between 30% and 100% (70,74). They are more likely to present with long thoracolumbar frontal curves. Type I is usually fatal due to respiratory failure by age 2. This early mortality has historically limited the importance of spinal curvature in care of the child. However, given the prevalence of curvature and the underlying weakness of the respiratory muscles, treatment should begin early. Scoliosis in the X-linked Duchenne muscular dystrophy (a disorder in the production of the protein dystrophin due to a defect at chromosome Xp21.2, 12q21) has a similar prevalence, 33% to 100% (74) with a 95% likelihood of scoliosis by the time the patient becomes wheelchair dependent (70). The curves may progress as much as 16 to 24 degrees/year and are also often long thoracolumbar curves, although double major curves are also seen (70).

In addition to decreased pain perception due to afferent dysfunction, people with Riley-Day syndrome have decreased tear production, no flare reaction in response to histamine injection, absence of tongue papillae, decreased to absent deep tendon reflexes, hypertension, and postural hypotension. About

86% of patients will have some form of spinal deformity. Of that group, 53% will have scoliosis, 44% will have kyphoscoliosis, and 4% will only have kyphosis (75). The prevalence of deformity is the same in males and females. Curves present early and tend to be rigid. Left thoracic curves are more common than in patients with idiopathic scoliosis (70). In Friedreich's ataxia, which has elements of afferent dysfunction and central dysfunction, there is also a very high prevalence of curvature, between 75% and 100% (70,76,77). In one study, the majority (57%) were double major curves. The remainder were thoracolumbar (14%), thoracic (7%), lumbar (4%), and small multiple curves (11%) (77). Of interest is the finding of one group of Friedreich's ataxia patients followed up for 10 years; they appeared to divide into two subgroups. One (55% of patients) had classic neuromuscular curves with progression of at least 60 degrees. The other group appeared to have idiopathic scoliosis with nonprogressive curves of less than 40 degrees.

Cerebral palsy is the most common congenital/neonatal central nervous system disorder associated with spinal deformity. There is a 15% to 68% prevalence of spinal curves (70,78). Curves are more common in quadriparetic cases and when dysfunction is more severe. As the patient gets older, it is more likely that curve will be detected (78). There is a negative correlation between ambulation and spinal deformity. The role of pelvic obliquity in the development of spinal curves is often debated, especially given the prevalence of hip subluxation and dislocation in cerebral palsy. Given the association between limitations in ambulation and spinal curves, it is reasonable to consider the role of pelvic obliquity and to address conditions such as hip deformity which may produce the obliquity. The amount of progression in adulthood is almost doubled (from 0.8 to 1.4 degrees/year) in untreated curves that are more than 50 degrees by the time the child achieves skeletal maturity. Thoracolumbar curves are more likely to progress than other curves, and scoliosis is often associated with thoracic kyphosis and lumbar lordosis (78).

As mentioned above, meningocele can present with aspects of both peripheral and central nervous system dysfunction, depending on the level of the lesion, as well as bony deformities. Spinal deformity is present at birth in 20% of patients and 51% will develop some spinal deformity. If the meningocele is above L2, the likelihood of spinal curvature increases to 87%. Curve presentations include scoliosis in 77% of patients, lumbar lordosis in 57% of patients, and thoracic kyphosis in 23% of patients (79).

### Acquired

The most common acquired cause of neuromuscular spinal deformity is spinal cord injury in children and adolescents. The likelihood of curvature increases as the age of onset decreases. Preadolescents have a 97% likelihood of acquired spinal deformity. The prevalence reduces to 78% in 14 year olds, 57% in 15 year olds, and 50% in 16 year olds (70). Curvature is not common in adults with spinal cord injury unless there is underlying bony instability.

Although syringomyelia may be congenital, it also may be due to trauma, with or without detectable spinal cord injury. It may also occur as a result of infectious processes such as meningitis or myelitis. Up to 85% of persons with syringomyelia will have scoliosis. Fortunately, most curves are less than 50 degrees in magnitude (70).

Neurofibromatosis is the most common benign tumor associated with spinal deformity. Neurological neoplasms causing spinal curvature are otherwise uncommon. Curvature is more common in NF-1 (von Recklenhausen), with scoliosis and/or kyphosis occurring in 5% of cases (80). There appears to be two types of curve associated with NF. One seems more like idiopathic scoliosis and may be associated with the presence of pseudomeningoceles (80). Curvature can also be due to paraspinal, plexiform neurofibromata impinging on neural structures and/or paraspinal soft tissues. Nonspine complications of NF such as spastic hemiparesis or asymmetric limb hypertrophy can result in spinal deformity. Curvature can also occur as a result of scarring due to radiation fibrosis after treatment of the neurofibromata.

## IDIOPATHIC SCLIOSIS

The etiology of the most prevalent cause of scoliosis is still unclear. Between 1.5% and 3% of the population has frontal spinal curvature greater than 10 degrees, meeting the SRS criteria for pathological scoliosis (81). This represents between 80% and 90% of all scoliosis (53,82). A familial association has been observed in a small minority of these cases, and, more recently, a number of genetic polymorphisms have been associated with some of these familial cases of idiopathic scoliosis (83,84). We previously mentioned many factors that can be involved in producing spinal curvature in the section on the general pathophysiology of scoliosis. Studies have suggested that a number of these factors may be involved in what is still classified as idiopathic scoliosis. Yarom et al. (85) have demonstrated asymmetric abnormalities in deltoid muscle including abnormal ratio of type I/type II fibers, with less type I fibers on the concave side of the curve and a myopathic recruitment pattern more prevalent on the concave side on needle EMG. Some association with rotational trunk strength has

also been seen (86). Goldberg and Dowling (87) have shown differences in cerebral lateralization in girls with scoliosis. As opposed to controls, they were more likely to have uniform handedness and footedness. Other studies (38,40,82,88) have suggested that balance and vestibular function may be factors. Papaioannou et al. (89) have shown a positive correlation between leg length discrepancy between 1.2 and 5.2 cm and nonprogressive lumbar scoliosis. A recent study has suggested an association between sacropelvic bone morphology in the frontal plane and scoliosis (90).

Although the etiology of idiopathic scoliosis is not yet fully elucidated, a better understanding of the condition can be appreciated by categorizing the condition based on the age of onset of the curve (Table 34-4).

### Infantile

By definition, the onset of this condition occurs before age 3. Most reported cases of infantile idiopathic scoliosis have been in Europe; the condition is quite rare in the United States (81). Especially given its rarity, it is important to first rule out one of the other causes for scoliosis discussed in the sections above, before making this diagnosis. The condition is usually benign, with 80% to 85% resolving spontaneously. Concern about progression should be raised if the curve is associated with a large difference in the angle formed at the connection of the rib to the vertebra (rib-vertebral angle) on the convex side versus the concave side of the curve (50). Smaller, more rigid curves are also more likely to progress (81). Since infants cannot stand and a supine film may result in false positives due to the child wiggling on the table, the definitive diagnosis of infantile idiopathic scoliosis requires a radiograph taken with the baby in a suspended position (81). Curves of less than 25 degrees with a rib-vertebral angle difference of less than 20 degrees can be monitored with radiographs every 4 to 6 months until the curve resolves and then every 1 to 2 years until the child reaches skeletal maturity. Larger curves are usually managed with a body cast and progressed to a molded orthotic once the child is older and the rate of growth slows. If the curve still progresses, surgery must be performed, but is delayed for as long as it is safe to wait, in order to allow for more spine growth. This is also one of the few instances where spinal surgery may be done

**TABLE 34.4** Types of Idiopathic Scoliosis

Type	Age of Onset	Percentage of All Idiopathic Scoliosis (%)	Male:Female Ratio	Common Curve Pattern	Usual Side of Curve Vertex	Usual Outcome
Infantile	<3 y	1	Males > females	T or T-L	L	May spontaneously resolve
Juvenile	3–10 y	12–21	Equal until 6 y then 1:8	T, double major, T-L	R	Usually will not spontaneously resolve
Adolescent	10 y-skeletal maturity	80–90	1:5	T, double major, T-L	R	Dependent on age of onset and size of curve

without fusion, with repeat surgeries to continue lengthening the spine (81).

### Juvenile

The middle group of idiopathic scoliosis is more diverse. Although, by definition, this category includes children over 3 years of age and less than the age when signs of physical maturity start to become apparent, it may actually represent two populations. The first population can be thought of as “late infantile” and the other group as “early adolescent” (81). Additionally, it is important to note that between 10% and 15% of scoliosis in children between 3 and 10 years of age may be associated with spinal cord anomalies, such as syringomyelia (50). Thus, as in any presumed idiopathic scoliosis, underlying conditions must first be ruled out.

The rate of curve progression is variable. Some report that approximately one third of curves will not progress. Of the two thirds that do progress, half will only need orthotic intervention, while the other half will eventually need surgical fixation (81). In the juvenile group, clinical and radiographic monitoring every 4 to 6 months is considered acceptable for curves less than 25 degrees. Curves beyond 20 to 25 degrees will require active intervention, beginning with orthotic management.

### Adolescent

Strictly defined adolescent idiopathic scoliosis consists of curves whose onset is after the initiation of puberty. As noted above, there are similarities between children with later onset juvenile scoliosis and adolescent scoliosis. This has led many to postulate that adolescent scoliosis likely begins in childhood but is not detected until the adolescent growth spurt begins (81). Given the prevalence of scoliosis in the population, the U.S. Preventative Services Task Force has recommended that adolescents be screened at school for scoliosis. The Adam’s bending test (see “Clinical Assessment” section above) is used for screening (50). Of those children screened positive, 3% to 9% have curves that progress to a need for active treatment (91).

To properly plan treatment for a patient with adolescent idiopathic scoliosis, it is important to be aware of the size of the curve at onset (which is positively correlated with progression) and the age and level of maturity of the patient (which is negatively correlated with progression) (81). Physical maturity can be assessed using the Tanner scales (which use external signs of sexual maturity), Risser’s sign (which is an indication of the degree of epiphyseal closure at the iliac crest), or formal bone age radiographs of the hands. Curves can be observed until they get to 20 (50) or 25 (81) degrees. The patient should have clinical and radiographic follow-up every 4 to 6 months. Patients with curves that are over the limits mentioned above or progress more than 5 degrees during the interval between follow-ups should begin orthotic management. If the curve continues to progress to more than 40 degrees before the patient achieves skeletal maturity, planning for surgery should begin (50,81).

## DEVELOPING A PHYSIATRIC TREATMENT PLAN

### Is There a Role for Therapeutic Exercise?

Most research has shown that therapeutic exercise is unable to stem the progression of curves in idiopathic scoliosis (92), and the studies that show a lack of effect have shown that this is not simply attributable to problems with compliance with the exercise program (92). Exercise alone has also not been able to correct the posture in patients with Scheuermann’s kyphosis (93). Unfortunately, as is common in research into the effect of exercise modalities in the treatment of disabilities, the literature is neither extensive nor very definitive. A group of researchers, many affiliated with the Scroth Clinic in Germany, have recently formed an organization called the Scientific Society on Scoliosis Orthopaedic and Rehabilitation Treatment (SOSORT) (94). This group is supporting research into the use of neuromuscular exercise to prevent curve progression, much of it based on the method developed at the German clinic. It will be worthwhile to monitor the progress of this research and, depending on the results, consider integrating the techniques into clinical practice. Since the exercises appear to be benign, at least for patients with idiopathic scoliosis, it would be unlikely that they would cause any harm if administered early in curve progression, so long as other, more accepted treatments are not neglected. It would be less wise at this time to consider these exercise techniques to stem progression of scoliosis in more complex pathologies such as those with neuromuscular or inherited multiple system involvement.

Putting aside the controversy above, most experts would agree that there are roles for exercise in the treatment of spinal curvature. Although exercise cannot stop curve progression, no scoliosis is without the risk of secondary morbidities. For example, patients with idiopathic scoliosis (especially under orthotic management) run the risk of core muscle weakness. As such, abdominal and gluteal strengthening exercises should be done to prevent deconditioning and atrophy. In addition, range-of-motion exercise of the hip flexors should be done to prevent contracture (92). In adults with degenerative scoliosis, exercise to improve trunk posture and alignment may prevent the development of pathological curvature. Since many adult spinal conditions are associated with pain, exercise to restore range of motion and strength should begin as soon as pain has been controlled in order to return the person to his or her premorbid functional state (95). Therefore, it should be clear that exercise has a role in the treatment of spinal curvature. That role is primarily to prevent secondary morbidities and to reduce the adverse influence of extraspinal processes (such as asymmetric limb joint contractures) on a progressive spinal deformity.

### Physical Modalities

Unfortunately, the literature on the use of physical modalities as a primary treatment to stem the progression of spinal curvature is at least as limited and pessimistic as that on the use

of therapeutic exercise. Traction was the traditional treatment for spinal curvatures before the development of spinal orthoses (96). The theory behind the use of traction was that it would “stretch out” the curves, and the hope in more modern studies was that it could make surgery more effective. However, research in traction in idiopathic curves has not shown any advantageous effect (53). In the 1970s and 1980s, interest in electrical stimulation as a treatment for scoliosis grew. The hope was that electrically induced contraction of the paraspinal muscles on the convex side of the curve would stabilize and straighten the spine (50). Studies have tried both surface and implanted electrodes. Although the early studies suggested a positive effect, more recent longer studies using natural history controls have shown no effect on curve progression (81). Instrumental EMG biofeedback has been even less convincing as an effective treatment option. This is not surprising, considering that direct stimulation has been ineffective. It is hard to develop a sound theory to postulate an effect from spinal manipulation and, in fact, there have also been no convincing studies demonstrating an effect on progression from treatment with spinal manipulation (81,97).

Therefore, similar to therapeutic exercise, the role of modalities is secondary in spinal deformity. Temperature modalities should be used symptomatically, keeping in mind the contraindications against the use of deep heating modalities if spinal hardware is present, the patient is a child under the age of skeletal maturity, or there is a neoplastic process. Massage, electrical stimulation, traction, and/or spinal manipulation should also be considered only for symptomatic treatment, applying the same principles that the physiatrist would use in the treatment of other conditions.

### Orthotic Management

It should be apparent by now that the mainstay of nonoperative, physiatric treatment of spinal deformity is spinal orthotics. The goals of the use spinal orthoses are no different than orthoses used in the appendicular skeleton, which are to immobilize and/or correct the position of the joint(s) to be controlled. The simple laws of Newtonian physics, which requires three points of fixation to achieve joint stability, are no different in the spine. However, the very nature and complexity of the trunk make the biomechanics behind spinal orthotic design much more complex since (as the reader may recall from the discussions in previous sections) the spine is a series of semirigid linkages, which are connected by tissues that function like springs. Each link has six degrees of freedom, making control of movement from an external source quite difficult. In addition, these linkages have different stiffness properties at different spinal levels due to the effects of their attached structures, such as the ribs (which increase the stiffness of the thoracic spine to bending by 200%). To further complicate things, the spinal column is suspended within the body. Tissues including muscles, other bones, air, water, viscera, and fat separate the spine from the orthosis attempting to act upon it. These tissues are, of course, not of uniform stiffness.

The softer tissues will not transmit as much of the force of the brace to the spine. In some diseases, such as osteogenesis imperfecta, even usually stiff structures such as the ribs cannot safely accept the forces required to be transmitted to the spine without risk of fracture and/or deformation. Lastly, the skin is the point of contact between the patient and the orthosis. Therefore, the forces must be applied through the skin, which has a limited tolerance to pain. Many braces also cover most of the trunk, limiting the ability of the skin to effectively perform its transpiration function, and the orthosis can produce contact dermatitis and/or fungal infections (53).

Given the challenges recounted above, it may be a wonder to the reader that orthoses work at all. Despite the challenges, spinal orthoses are able to apply balanced perpendicular forces to create a (un)bending moment in the curve, focused at the curve vertex. Force must be applied on the concave side above and below the level of the vertex of the curve and it is countered by a force applied on the convex side at the vertex of the curve (53) (Fig. 34-11). In the living human system, the forces not only provide an immediate effect on the spine but also may promote biological tissue “creep” causing adaptation of the spinal tissues to the forces applied, resulting in a long-term effect from the brace (53). As a result of

**FIGURE 34-11.** Three points of fixation are required to exert a force to counter a curve. (Courtesy of Donald Bliss and Alan Hooftling of the Medical Arts and Publications Branch, NIH.)

the geometry of the spinal column, as the orthosis corrects the spine, the correction itself will propagate improved spinal stability, which will also slow progression. It has been shown that decreasing a curve from 45 to 30 degrees will increase the stability of the spine from 20% to 50%. A decrease in curve from 30 to 20 degrees will further improve the stability to 80% (96). In addition to the primary effect of spinal orthoses, they also improve endpoint control, which reduces sway in the neck and/or pelvis and helps bear some of the spine's transverse load. These effects may also be helpful in controlling spinal deformity (96).

Most of the research on brace effectiveness has been from the idiopathic scoliosis literature, which has shown that it is more effective in preventing curve progression than electrical stimulation or observation of progression (98). There is a dose-response relationship between wearing time and effectiveness (especially in curves >35 degrees), with studies showing that full-time wear time (23 hours/day) is more effective than 8- to 12-hour wear times (99).

In light of the biomechanical complexity, it is not surprising that there are many different bracing options for spinal curvature. Most of the literature on bracing options comes from studies of idiopathic curves, so the physiatrist needs to apply the knowledge and principles gleaned and apply them to other conditions, based on a good understanding of the biomechanics discussed above. However, to help with decision making, Table 34-5 reviews the role of orthotic management in scoliosis of differing etiologies and the type of orthotic which can be considered.

There are two basic types of rigid braces. The “gold standard” is the Milwaukee type cervical-thoracic-lumbar-sacral orthosis (CTLSSO). In addition to applying a bending moment at the vertex of the curve, it produces a distraction force on the spine by virtue of being anchored at the chin and the pelvis (53). Meta-analytic studies have shown the Milwaukee to be the “most successful brace in affecting outcome and preventing progression” (99). The obvious question is, if the CTLSSO

is so good, why are there any other braces? The answer is that the features which give it the increased stability (the chin and pelvic anchoring) make it less comfortable to wear and less cosmetically acceptable.

As a response to the problems of cosmesis and comfort with the Milwaukee, lower profile thermoplastic molded thoracic-lumbar-sacral orthoses (TLSO) have been developed. The Boston brace is a prefabricated unit with added pad components to apply the forces (100). The Wilmington (101) and CAD/CAM braces are custom molded with the force “pads” built into the mold. These orthoses are not effective for curves whose vertex is higher than T<sub>8</sub> because they cannot provide a long enough proximal lever arm to achieve effective proximal fixation (81). There have been no definitive studies comparing these orthoses to the Milwaukee, but they have all been shown to be more effective than electrical stimulation or observation. The Charleston Bending (102) (and similar Providence Night-Time (103)) brace is a specialized TLSO where the brace is shaped to overcorrect the curve. This brace is only worn while the patient is sleeping. The hope is that there will be improved compliance with decreased wearing time. It may be effective in long “C” curves but has been shown to be less effective than the Boston brace in such curves (96). However, it may be more effective in lower (thoracolumbar and lumbar) curves (104). Some groups (105,106) are experimenting with rigid orthoses with decreased quantities of materials and claim to get similar results as the Boston type braces. Whether these styles will be more effective and/or more comfortable is yet to be determined.

Recently, a new nonrigid TLSO has been developed. The SpineCor is considered by its inventors to be a “dynamic” orthosis (107). It is made up of a series of elastic bands and pelvic girdle and is to be worn 20 hours/day with two separate 2 hour rest periods out of brace. It is less restricting but more complicated than the rigid thermoplastic TLSOs. There is only limited research on this device to date. The available research is limited to the group which developed the brace.

**TABLE 34.5** Role of Orthotic Management in Spinal Deformity of Different Etiologies

Curve Etiology	Role of Orthotic Management	Type of Orthosis
Idiopathic	Correct and prevent progression	Rigid with three-point fixation
Myopathic/lower motor neuron	Limited, since it cannot stop progression Ambulatory patients—slow progression Seated patients—comfort and support	Rigid Soft (and must take care that orthosis does not decrease pulmonary function)
Upper motor neuron	Slow progression in seated patients (likely to restrict function in standing patients too much)	Rigid
Congenital bony dysfunction	Slow or stop progression in long flexible curves	Rigid
Ligamentous dysfunction	Insufficient literature; might be able to control curve but effect would be limited by deformation of intervening structures. Consider limiting use for support and comfort	Soft
Degenerative	For comfort and support, will not likely affect curve	Rigid or semirigid

Their initial study was limited to children with idiopathic curves between the ages of 6 and 14, with initial curves of 15 to 50 degrees. The majority of the curves were less than 30 degrees at diagnosis. Only 29 patients completed 2 years of follow-up after treatment. The results were not compared to natural history controls. The results, however, are promising, with decreased curves in 55% of the patients, stability in 38%, and progression in only 7%. This same group has continued to follow an expanded cohort, again with promising results but not in comparison to other treatment or bracing options (108). (Fig. 34-12 shows examples of each of the brace archetypes.)

## SURGICAL TREATMENT OPTIONS

Extensive discussion of surgical techniques, approaches, and instrumentation is beyond the scope of this chapter. The reader who is interested in more details of surgical treatment of spinal curvature is urged to reference an orthopedic surgical textbook focused on spine surgery, many of which can be found in the reference list for this chapter. Physiatrists need to have a sufficient understanding of spinal surgery to advise and advocate for their patients both preoperatively and postoperatively. This section focuses on the general principles behind surgery for spinal deformity and archetypical examples of spinal instrumentation.

The goal of most spinal surgeries is to realign the spine as much as possible with rigid surgical instrumentation and then allow the body to heal, fixed in a position of better alignment. This occurs by the postoperative fusing of the vertebrae. The surgeon must balance the need to fuse the spine for stability with the need to preserve as much motion as possible (109). For stability, fusions are preferably done beyond the ends of the curve at points within the stable zone (defined by Harrington as the area between two lines drawn upward and perpendicular to the pelvis beginning at the sacral pedicles) (9). In some conditions, there are additional considerations. For example, due to the loss of motor control in neuromuscular pathologies, the

surgeon may choose to start the instrumentation and fusion at the pelvis. In congenital bony scoliosis, the surgeon must not only stabilize the spine but also correct the imbalance in bony growth. In conditions where the bone stock is abnormal, such as in osteogenesis imperfecta, the surgeon needs to consider how to best stabilize his/her instrumentation until good bony fusion is achieved.

Spinal instrumentation can apply only a limited range of forces. In the vertical plane, hardware can distract the concave side of a curve and/or compress the convex side of the curve. Distraction becomes more effective as the curve gets larger, whereas compression becomes more effective as the curve gets smaller. Translational forces can also be applied at the vertex of the curve in a manner similar to the way a spinal orthosis works, but without the complications of the intervening tissues. In kyphosis, cantilevered (like a springing diving board) forces can be applied to promote extension at the proximal portion of the curve. Torsional forces can also be applied to attempt to derotate the vertebrae by applying asymmetric force to the hardware anchors at a given spinal segment (109).

The Harrington system of rods, anchored by hooks on each end, was the first successful spinal instrumentation system. At first, one rod was placed on the concave side to distract the curve. As the procedure matured, a second rod was added on the convex side to compress the curve. The Harrington system only produces the vertical forces of compression and distraction. Since it is anchored only at the top and bottom of the curve, it is not as stiff as more modern systems and, thus, more prone to hardware failure and requires longer postoperative stabilization. Cotrel DuBosset instrumentation is the archetype of the category of hardware developed to address the stiffness issue of the classic Harrington rods. It has interlinked rods with hooks at multiple levels and is quite stiff. Luque rectangular instrumentation was one of the first systems with an option to apply a derotational torsion force. It is composed of two L-shaped rods, which form a rectangle encompassing the curve. It is attached by wires wrapped around and anchored to the left and right lamina at each segmental level. It is also stiff but can fail due to

**FIGURE 34-12.** The archetypes of spinal orthotic options. (Courtesy of Milwaukee-Bertil Holmberg, Boston-Boston Brace International, Inc., Charleston-Charleston Bending Brace Foundation, SpineCor-Spine Corporation.)

**FIGURE 34-13.** Archetypes of spinal fixation instrumentation. (Courtesy of Harrington-Keith Bridwell, MD, Cotrel-DuBosset-Medtronic Sofamor Danek, Luque-William Lauerma, MD, Halm-Zielke-Prof. Henry Halm, MD.)

wire breakage. Halm-Zielke instrumentation is one archetype of the newer systems which are fixed at each segmental level by left and right pedicle screws with short linked rods connecting each spinal segment. It not only is quite stiff but also can more easily control curves with complex segments owing to the flexibility in how each rod is connected to the next. However, it is a more complex system with the increased surgical challenge of safely installing the pedicle screws (Fig. 34-13).

The Halm-Zielke system is also representative of a surgical trend toward an anterior approach to stabilization. Although recent studies have suggested greater curve correction (110,111), it is unclear whether this difference is functionally significant and worth the potentially increased morbidity associated with opening the chest cavity and possibly damaging the sympathetic nerve chain (112). However, surgical techniques are constantly advancing: morbidity from anterior approaches may decrease as a result of thoroscopic techniques (113), and morbidity from posterior approaches may decrease as a result of percutaneous techniques (114). Surgeons have also had a renewed interest in fusionless techniques, primarily in growing children who would lose height and chest cavity size if fused at a young age (115–117).

## POSTOPERATIVE REHABILITATION

Unfortunately, there is not an extensive published literature on rehabilitation after spinal curve correction surgery. The primary challenge is to restore the patient to full function as early as possible without compromising the integrity of the surgical intervention. Spine surgeons have accepted the general principle of early mobilization to prevent deconditioning and other secondary postoperative morbidities. The need for postoperative orthotic management should be determined by the surgeon who knows how secure and stable his/her instrumentation is. The time after surgery until the brace can be removed should also be determined by the surgeon, based on the biomechanical success of the surgery. The physiatrist should apply the general principles of postoperative rehabilitation to help return the patient to normative daily life function. This should include

preventing secondary deformities, such as contractures, due to decreased mobility, providing adaptations to best perform activities of daily living while the patient is in orthosis or has mobility restrictions, addressing any underlying pathologies and their functional implications, and reconditioning the patient once the spine is stable. The specific issues that need to be considered include avoiding stress on the healing spine by avoiding strengthening exercises or range-of-motion exercises in regions that will apply significant forces to the healing spine.

## CONCLUSION

Physiatric management of spinal curvature requires a solid understanding of spinal anatomy, physiology, and biomechanics. This knowledge should be applied to understanding the way various disease mechanisms may affect the spine. Applying the principles of comprehensive history taking and physiatric examination with objective measurements, including appropriate radiographs, should allow physiatrists to sufficiently understand the diagnosis causing their patients' spinal curvature and the pathophysiology of that condition and how it is affecting the spine. With this knowledge and an understanding of the role of physiatric modalities and surgery in the treatment of the patient, the physiatrist should be able to develop an appropriate rehabilitation program to help control and reduce the patient's spinal curvature and optimize his or her quality of life.

## Upper Extremity Soft-Tissue Injuries

Upper extremity pain is a leading cause of physician visits in the United States. This is particularly prevalent in sports and the workplace, contributing significantly to disability and lost productivity. Along the spectrum of potential conditions, musculoskeletal soft-tissue injuries are the most common. Despite a wealth of investigations on soft-tissue injury, there remains an incomplete understanding of what these injuries are and the sequence of events leading to their development. A detailed understanding of the relevant functional anatomy and potential mechanisms of injury allows for the most accurate diagnosis and is directly related to the likelihood of successful treatment. This chapter describes a classification of soft-tissue injury, identifies potential mechanisms of injury, and presents a model for successful rehabilitation. Injuries specific to the shoulder and elbow are considered.

The soft tissues constitute a diverse group of connective tissues, including ligament, tendon, muscle, cartilage, fascia, synovium, articular cartilage, adipose tissue, and intervertebral disc. Collectively, connective tissues function as support for the soft tissues, transmit and distribute mechanical forces, and act as a conduit for neurovascular structures. They are composed of collagen fibers; ground substance, primarily in the form of proteoglycans and water; and specialized cellular components. Although the connective tissues share common structural features, each has unique cellular and biomechanical properties and, therefore, demonstrates individual responses to injury and healing (1). Loose connective tissue, for example, is poorly organized and typically seen in subcutaneous tissue, small joint capsules, and fascial borders. Tendons and ligaments are composed of dense, organized connective tissue, with a larger proportion of collagen fibers arranged according to their biomechanical requirements (2) (Fig. 35-1). Tendons, in particular, are subjected to great tensile stress because they function to transmit force from muscle to bone. The tensile strength of tendon is generally double that of its associated muscle (3,4). This likely accounts for the greater incidence of injury at musculotendinous junctions. There are numerous factors influencing the integrity of soft tissues, including age, sex, temperature, body weight, exercise, nutrition, drugs, immobilization, injury, and systemic illnesses such as inflammatory arthritis and the collagen vascular disorders.

Soft tissues are susceptible to failure under conditions of stress and strain. The most common mechanisms of injury include acute trauma and repetitive overuse or overload. Musculotendinous structures are especially vulnerable to

failure from sudden overloading, as with forceful muscular contractions, particularly when weakened as a result of concurrent illness (connective tissue disorders) or medications (steroids). More commonly, repetitive overuse leads to an insidious onset of pain, inflammation, and ultimately, structural failure. In the context of persistent or uncontrolled stress, a cycle may occur in which structural maladaptations develop in the damaged tissue, setting the stage for further injury and chronic inflammation (Fig. 35-2).

The three phases of soft-tissue healing include the cellular response to injury; repair and regeneration, as immature collagen is laid down; and scar remodeling, a process that may continue for years (5). Understanding this sequence of events has direct implications on the success of treatment and rehabilitation. The type of injury, age, vascularity, nutrition, genetic and hormonal factors, and activity level influence successful healing of soft tissues. Acute injuries typically have a sudden onset, are associated with a classic inflammatory reaction, and tend to follow a predictable course toward resolution. Chronic injuries (duration longer than 3 months) are often marked by an insidious onset of pain, less intense inflammation, progressive functional impairments, and a tendency toward reinjury. Advanced age is associated with decreased collagen synthesis and impaired tendon healing. Exercise improves both the mechanical and structural properties of tendon as opposed to inactivity, which favors collagen degradation and decreased tendon strength.

The nature and classification of soft-tissue injury, as well as the injury response, are specific to the involved structure (1). Ligament sprains have been classically defined as grade I, II, and III based on the degree of tissue damage and separation (Table 35-1). Grade I sprains demonstrate negligible loss of structural integrity, display minimal signs of inflammation, and generally recover quickly and completely. In grade II sprains, partial rupture of the ligament is associated with significant pain and inflammation. Functional recovery generally occurs within 4 to 6 weeks; however, pain is often experienced for months after the injury, and the tensile strength of the involved tissue is reduced up to 50% (6). Grade III injuries are often associated with prolonged healing time, chronic instability, susceptibility to recurrent sprains, and impaired proprioception of the involved joint.

Tendons are susceptible to injury through the same mechanisms of tensile overload and repetitive overuse (7,8). Tendons are particularly vulnerable to failure when tension is applied quickly or obliquely, the tendon is tense before trauma, the

**FIGURE 35-1.** Tendon: structural characteristics.

attached muscle is maximally innervated, the muscle group is stretched by external stimuli, and the tendon is weak in comparison to its muscle (9). Tendon injuries, or tendinopathies, can be classified according to a sequence of overlapping pathologic conditions: inflammation, degeneration, and rupture (Table 35-2). Paratenonitis refers to inflammation of the paratenon. When the structure is associated with a synovial lining, the condition is described as tenosynovitis. The term *tendinitis* refers to injuries and inflammation specifically involving tendon. *Tendinosis* describes a chronic process of intratendinous

**FIGURE 35-2.** Repetitive soft-tissue injury cycle.

degeneration and atrophy, minimal or no inflammation, and loss of structural integrity, potentially leading to tendon failure (10–12). Inflammation of the paratenon may occur concomitantly with tendon atrophy, referred to as paratenonitis with tendinosis. A functional classification of traumatic tendinitis is particularly useful because the degree of disability correlates well with the extent of injury (Table 35-3). This grading system also provides objective parameters for following treatment and rehabilitation.

Muscular injuries are particularly common in sports. These are typically classified as contusions, strains, avulsions, and delayed-onset muscle soreness. Contusions result as a direct blow and are graded as mild, moderate, or severe based on the degree of soft-tissue swelling, motion restriction, and functional impairment. Intramuscular contusions tend to be more severe, resolve slowly, have more extensive scarring, and are susceptible to developing myositis ossificans (13–16). Muscular strains result from overstretching or peak contraction of the musculotendinous unit, particularly during eccentric muscular contractions. These injuries tend to occur more commonly at the musculotendinous junction. The classification is similar to that of muscular contusions.

**TABLE 35.1** Ligament Sprains

Grade	Signs and Symptoms	Functional Implications
First degree	Minimal pain and swelling No ligamentous instability Minimal localized tenderness	No significant loss of function Bracing often unnecessary Rapid return to activity
Second degree	Significant pain and swelling Subtle structural instability Occasional joint effusion	Protective bracing indicated Significant activity limitations Susceptible to recurrence
Third degree	Marked swelling and hemarthrosis Structural instability	Immobilization indicated Surgery may be required Prolonged functional limitation

**TABLE 35.2 Classification of Tendon Injuries**

Injury	Characteristics
Paratenonitis or tenosynovitis	Inflammation of the paratenon with associated pain, swelling, and tenderness
Tendinitis	Inflammation of the tendon with associated vascular disruption and inflammation
Tendinosis	Intratendinous atrophy and degeneration with a relative absence of inflammation; a palpable nodule may be present over tendon
Paratenonitis with tendinosis	Acute inflammation superimposed on chronic tendinitis
Partial or complete rupture	Acute inflammation is often superimposed on chronic inflammation with tendinosis

The injured muscle generates reduced peak tensile loads and contractile forces, up to 50% of its strength. Contractile forces begin to recover as soon as 1 week after an acute strain; however, there is often prolonged and sometimes permanent loss of complete contractile ability (17–19). Therefore, the functional ability of a patient recovering from a muscular strain may be significantly limited, and premature return to activity may increase the risk for further injury. Delayed-onset muscle soreness typically occurs within the first 24 to 48 hours after an intense bout of exercise that often involves repeated eccentric muscular contractions. Both inflammatory and metabolic mechanisms have been proposed for muscle damage in this condition (20,21). In most cases, the condition is self-limiting but occasionally requires activity modification and anti-inflammatory medication.

It is useful to approach the treatment and rehabilitation of soft-tissue injuries through a conceptual framework that begins with establishing the most anatomically correct diagnosis and ultimately returns the patient to normal athletic or occupational performance (22–26) (Table 35-4). Protecting the injured site and controlling pain and inflammation set the stage for an active therapy program geared toward improving the flexibility, strength, and endurance of the damaged tissue and entire kinetic chain. This also takes into account other factors that may be associated with the development and persistence of symptoms (Table 35-5).

**TABLE 35.3 Tendon Injuries: Functional Scale**

Grade	Symptoms
1	Pain after exercise, subsiding within 24 h
2	Minimal discomfort with exercise, without activity limitation
3	Pain that interferes with exercise
4	Pain interfering with activities of daily living
5	Rest pain that interfering with sleep

## SOFT-TISSUE INJURIES OF THE SHOULDER

Two primary factors make the shoulder joint particularly susceptible to soft-tissue injuries. First, the surrounding soft tissues constitute the main support system for the upper extremity. Second, the small glenoid fossa allows for a large range of motion that often permits excessive mobility, thereby straining the soft tissues and stressing the joint. Injuries of the shoulder can be broadly classified as those that result from more acute processes, such as direct trauma, and those that occur from more repetitive tasks, such as bursitis and tendonitis. Overall, shoulder injuries are so common that they are second only to back injuries in disability costs associated with lost time (27). Understanding the complex anatomy and kinesiology of the shoulder is essential for accurate diagnosis and appropriate treatment.

### Anatomy of the Shoulder

The shoulder is composed of many joints, including the scapulothoracic joint, which is considered a functional joint. The glenohumeral joint is a synovial joint lined by the glenoid labrum, which provides a large contact surface to the glenoid fossa. Despite the large labrum, the humeral head comes into contact with only about one third of the glenoid fossa at any one time (28). The capsule of the glenohumeral joint is divided into three functional bands that are considered ligaments, aptly named the superior (SGHL), middle (MGHL), and inferior glenohumeral (IGHL) ligaments. Additional support is provided by the coracohumeral ligament (CHL) originating on the coracoid and inserting into the greater and lesser tuberosities. The acromioclavicular (AC) joint is another synovial joint made up of the distal aspect of the clavicle and the

**TABLE 35.5 Overuse Injuries**

Intrinsic variables	Age Flexibility imbalance Muscle imbalance/weakness Anatomic malalignment Genetic predisposition
Extrinsic variables	Training errors/poor technique Environmental factors Equipment factors

acromion and is supported by the coracoacromial ligament, the AC ligament, and the coracoclavicular (CC) ligament (composed of two smaller ligaments—the conoid and the trapezoid). Motion at the AC joint requires not only translation but also rotation for smooth movement of the shoulder. The last synovial joint involved in the shoulder is the sternoclavicular joint. The joint is bordered by the medial aspect of the clavicle and the manubrium of the sternum. There are four ligaments surrounding the joint: the anterior and posterior sternoclavicular ligaments, the costoclavicular ligament, and the interclavicular ligament.

The muscles of the shoulder and shoulder girdle can be divided into two major groups: those that stabilize the scapula and those that attach to the humerus. The stabilizers include the trapezius, levator scapula, rhomboids, serratus anterior, and pectoralis minor. These muscles allow for the stability of the shoulder girdle and provide a foundation for movement and force generation that is passed along the trunk into the arm for functional use. The muscles that attach to the humerus include the rotator cuff muscles (supraspinatus, infraspinatus, teres minor, and subscapularis), deltoid, teres major, pectoralis major, coracobrachialis, biceps brachii, and latissimus dorsi. These muscles provide the arm with most of its motion.

### Kinesiology of the Shoulder

Range of motion of the shoulder is accomplished by glenohumeral and scapulothoracic motions. The first 30 degrees of abduction is initiated by the deltoid muscle followed by a 2:1 ratio of movement, with the glenohumeral joint responsible for 120 degrees and the scapulothoracic motion supplying the additional 60 degrees. The humerus, however, needs to be in an externally rotated position to be able to obtain full abduction; otherwise, the tuberosity on the humerus impinges on the undersurface of the acromion.

Several authors have evaluated the kinematics of the scapula and its interaction with the humerus. Borstad and Ludewig (29) looked at scapular motion in both symptomatic and asymptomatic individuals. Through electromagnetic tracking, they were able to evaluate scapular tipping and internal rotation. They noted that in symptomatic individuals there was less upward rotation at lower humeral elevations and increased tipping at higher elevations when compared to controls. These same scapular changes were also noted in patients with multidirectional instability (30). There does not appear to be consistent findings with glenohumeral motion (31).

The muscles noted previously can be divided into functional groups. For example, internal rotation is accomplished by the subscapularis, latissimus dorsi, anterior fiber of the deltoid, pectoralis major, and teres major. External rotators include the infraspinatus, teres minor, and posterior fibers of the deltoid. Abductors include the deltoid, supraspinatus, trapezius, and serratus anterior. Adduction is accomplished by the subscapularis, infraspinatus, teres minor, pectoralis, latissimus dorsi, and teres major. Flexion of the arm involves the pectoralis major, biceps brachii, and anterior deltoid. Extension is

accomplished by posterior deltoid, teres major, and latissimus dorsi. Some muscles may contribute to motion based on the initial position of the humerus. For example, if the humerus is in a flexed position, the pectoralis may assist in early extension to the neutral plane.

## Disorders of the Shoulder

### Contusion and Myositis

Contusions are a result of blunt trauma to the soft tissue and may be difficult to differentiate from tears because both involve a significant amount of injury to the muscle fiber. Contusions can be divided into intermuscular and intramuscular types. Diagnostically, ultrasound or magnetic resonance imaging (MRI) may be helpful in determining the location of the injury. This may have clinical value because contusions and hematomas occurring between the muscles tend to disperse more easily along the fascial planes and result in an earlier return to function. Intramuscular lesions take longer to resolve because they are confined, and the inflammatory response is greater. These injuries also have a higher incidence of compartment syndrome (rare) and myositis ossificans associated with them. Myositis ossificans is the invasion of calcium and bony islands within the muscle. This process is usually accompanied by erythema, swelling, and a significant amount of pain. Radiographs early in the process may not reveal the ossification. If a compartment syndrome is suspected, release and drainage are critical to prevent long-term injury to the neurovascular structures.

### Instability

Laxity of the shoulder joint varies tremendously between individuals. A certain amount of laxity or movement of the joint is normal; this translation is needed for the joint to have the mobility and function that it needs. Laxity is also noted to be present in most asymptomatic adolescents and decreases with age (32). Instability as a pathologic process should only be explored if there are symptoms that correlate to the degree of motion noted at the joint. The labrum contributes to about 20% of the glenohumeral stability with the joint loaded (33). Anterior stability is maintained not only through the forces at the labrum and rotator cuff muscles but also along the capsule particularly at the MGHL and IGHL. The anterior forces when the arm is abducted 90 degrees are mainly counteracted by the IGHL. At angles closer to the body, the MGHL plays a larger role. Most dislocations occur in an anterior plane when the arm is abducted, thereby indicating that the area most likely to be involved in a traumatic dislocation is the IGHL (34). Posterior translation of the joint is significantly less common. The positions of the humerus that place the joint at greatest risk are flexion, adduction, and internal rotation. In this position, failure of several soft tissues is still required for dislocation to occur. The ligamentous capsule on the posterior aspect of the glenohumeral joint is underdeveloped; therefore, the support appears to be a combination of the anatomic position of the glenoid and the nearby SGHL, IGHL, and CHL along with the rotator cuff muscles themselves. Inferior translation is noted in the neutral

**FIGURE 35-3.** Apprehension sign.

position by the sulcus sign. As stated earlier, a certain degree of laxity is normal. The counteractive force of inferior translation in the neutral position is mainly provided by the SGHL and the CHL. As the arm is abducted, the resistive force at the IGHL is increased and is related to the amount of abduction. If the arm is also internally rotated, additional force is placed on this ligament. Superior translation is clinically insignificant because of the bony structure of the acromion.

Diagnosis of instability relies on the history and reproduction of symptoms with specific physical maneuvers. An apprehension maneuver is typically completed in the supine position, and anterior translation-type forces are applied to the humerus with the arm abducted to 90 degrees and externally rotated. A positive test is noted with pain and fear of subluxation expressed by the patient (Fig. 35-3). A relocation maneuver is also helpful to confirm the diagnosis. This is accomplished by a posterior force applied on the humerus with a reduction in symptoms or additional motion allowed in external rotation with a reduction in pain. Diagnostic tests that may be helpful include a scapular Y film and an axillary view for anteroposterior location of the humerus in relation to the glenoid.

### Acromioclavicular Joint Sprain

AC joint sprain usually occurs from a fall on an outstretched arm or a direct blow to the shoulder. Pain over the joint and increased joint mobility is frequently noted and may help to guide the diagnosis. In addition, there is pain noted on crossed adduction from compression of the joint and in the end range of abduction from the pull of the deltoid and trapezius. Typically, the diagnosis can be made clinically, but in some cases, an x-ray with a weighted view may be helpful. If gapping of the joint is seen, it can support the diagnosis. However, it should be noted that a negative x-ray does not preclude the diagnosis. AC joint strain and separations are divided into grades. Grade 1 is defined as pain at the joint; however, the ligaments are intact, and there is no subluxation

of the joint. Grade 2 is movement of the joint related to a tear in the AC ligament but not in the CC ligaments. Grade 3 indicates a tear through both AC and CC ligaments. Grades 4 to 6 are defined by displacement of the clavicle posteriorly, superiorly, and anteriorly, respectively. In addition, grade 6 displacement involves entrapment of the distal clavicle in the surrounding muscles. Typically, grades 1 to 3 are treated conservatively, whereas grades 4 to 6 require reconstruction. Reconstruction can also be considered in individuals with persistent pain from a grade 3 injury. Treatment of a grade 1 separation would include ice, sling and swath, or resting of the arm for a short period of time. Range of motion is progressed as tolerated, the supporting musculature is strengthened, and weight loading of the joint is avoided for about 6 weeks. A grade 2 injury requires a slightly longer rest period (up to 2 weeks) before returning to range and strengthening activities. Grade 3 injuries do not require surgical reconstruction. Although there may be some controversy regarding non-surgical management of these injuries, there are several studies that have demonstrated good outcomes with conservative treatment, and one study showed an earlier return to work and play when compared with the surgically treated group (35–38). Grades 4 to 6 are still thought to do better with surgical intervention.

### Bicipital Tendonitis

Activation of the biceps muscle is noted with elbow flexion and supination of the forearm. There is also some activity with abduction of the arm in an externally rotated position. The long head of the biceps is integrally linked to shoulder function and may assist the rotator cuff muscles with counteracting anterior and superior forces at the humerus. Its origin is at the supraglenoid tubercle and the adjacent labrum. It courses within the capsule and along the bicipital groove between the tubercles and is held in place by the transverse ligament. The biceps tendon is frequently involved with rotator cuff pathology and anterior laxity of the humerus. Tendinitis is common and usually associated with overhead activities. Clinically, palpation of the tendon and pain produced with resisted supination while the elbow is flexed and held against the trunk (Yergason's test) or with resistance of forward flexion with the elbow extended and supinated (Speed's test) are indicative of tendonitis (Table 35-6). The tendon has been noted to be swollen, stenotic at the transverse ligament, and frequently hemorrhagic. In addition, adhesions may develop in the area with ongoing inflammation. If the transverse ligament is lax or ruptured, the biceps tendon can sublux. This can be palpated, and the patient frequently reports a snapping sensation. Rupture of the tendon most commonly affects the proximal portion of the long head. Symptoms range from discomfort and weakness to a painful snap. Surgical intervention is considered in young, active individuals. Mariani and Cofield (39) evaluated conservative versus surgical intervention and noted the following: there was no difference in residual pain, elbow motion, strength of elbow extension, forearm pronation, or grip strength; the nonsurgical group usually returned

**TABLE 35.6** Tests Used in the Diagnosis of Shoulder Pain

Maneuver	Description	Implication
Sulcus sign	Inferior translation force at the humerus with retraction of the soft tissue above the humeral head	Laxity in the inferior capsule <sup>a</sup>
Apprehension and relocation	Patient supine with arm abducted to 90 degrees, externally rotated, and elbow flexed; anterior translation placed at proximal humerus Relocation with posterior force at proximal humerus with reduction in pain and greater external rotation	Anterior instability
Yergason's	Elbow is flexed and forearm supinated	Bicipital tendonitis
Speeds'	Arm is flexed with elbow straight and supinated; resistance is applied to arm flexors	Bicipital tendonitis
Hawkins'	Arm is abducted to 90 degrees and internally rotated, causing pain	Impingement of the supraspinatus tendon
Neer's	Arm is flexed to 90 degrees and internally rotated; patient resists downward force	Humerus slides superiorly and causes impingement
Painful arc	Pain noted on abduction from 60 to 120 degrees	Supraspinatus tendonitis
Drop arm	Arm placed in full abduction and patient asked to lower arm slowly; arm drops from midabduction	Supraspinatus full-thickness tear
Clunk	Translation of the humerus over the edge of the labrum	Glenohumeral instability or possible labral tear
Adson's	Pulse is palpated, and a drop in the pulse may be noted during inhalation, coupled with rotation of the head activating the scalene muscles	Possible thoracic outlet
Roos'	Hands repetitively opened and closed with arms abducted and elbows bent increasing vascular demand	Possible thoracic outlet

<sup>a</sup>A certain degree of laxity is considered normal in individuals. It is best to compare side to side for significant differences.

to activities, including work, more rapidly, albeit initially at a reduced capacity; and there was usually an associated loss of strength with elbow flexion (10%) and supination (20%), and many individuals were aware of this weakness. Therefore, if the patient is a young and active individual, surgical consultation is generally recommended.

### Bursitis

There are multiple bursae in the shoulder. The subdeltoid, subacromial, and subcoracoid bursae separate the rotator cuff and the acromial arch. They often communicate with each other, and the subacromial bursa can become inflamed in the younger athlete by direct trauma or in the older individual with overuse and cuff problems. This syndrome is typically painful and significantly limits abduction of the arm. Movements in other planes are typically unaffected. An injection of lidocaine and crystalline steroid into the subacromial bursa can be helpful as a diagnostic tool and therapeutic treatment for the bursitis.

### Impingement

The mechanism of injury involves repetitive motion from an abducted and externally rotated position to an internally rotated flexed position. This causes the tuberosity of the humerus to come under the arch of the acromion or along the coracoacromial ligament. These injuries are common in throwing sports and swimmers. It is usually associated with a painful arc (pain noted with abduction of the arm in

the range of 60 to 120 degrees). Impingement signs include Hawkins' maneuver, with the arm flexed, slightly abducted, and internally rotated, or Neer's sign, with the arm in full flexion at 90 degrees, internally rotated while resisting flexion (Fig. 35-4; see Table 35-6). These tests may help with the clinical diagnosis but are not specific to impingement. In addition, impingement is frequently associated with tendonitis of the supraspinatus and biceps tendons as well as degenerative changes in the rotator cuff. Neer (40)

**FIGURE 35-4.** Impingement sign.

described three stages of impingement. The first is noted to have edema and hemorrhage along the supraspinatus insertion. The changes usually occur in younger individuals (12 to 25 years of age) and are typically reversible. Stage II is associated with fibrosis, thickening of the coracoacromial ligament, and bony changes of the acromion. The last stage is most commonly seen in people older than 40 years of age and is associated with partial or complete cuff tears. Biomechanical studies have been done looking at scapular motion, specifically dyskinesis in the setting of impingement. Scapular dyskinesis is defined by Kibler (41) as the loss of control in the motion of scapular with respect to external rotation and retraction. This results in an anterior tilt of the glenoid, loss of maximal rotator cuff muscle activation, and reduced rotation of the acromion. All of these factors contribute to clinical impingement. His work on impingement and muscle coupling, which will be discussed later in the chapter, has contributed to effective rehabilitation of the shoulder.

### Rotator Cuff Tendonitis and Tears

The two main categories of rotator cuff tears are related to their mechanism of injury: traumatic and degenerative tears. Traumatic tears can happen at any age, but older people are more susceptible because of underlying degeneration. McNab (42) has defined an area in the cuff that is noted to have less vascularization, which may contribute to some of the changes noted. As we age, the cuff thins and becomes frayed. There is a 54% incidence of tears within the cuff in asymptomatic individuals older than 60 years (43). Calcific tendonitis is also a risk factor for cuff tears and frozen shoulder. This occurs more commonly in diabetic patients. The cuff can be evaluated with diagnostic ultrasound, arthrography, and MRI. Ultrasound is the least sensitive and can miss incomplete tears. MRI with T2-weighted images is highly specific for a full-thickness tear, whereas its sensitivity is less for partial-thickness tears. The use of arthrography can sometimes demonstrate extravasations of contrast in a partial-thickness tear, often missed with other imaging techniques. Symptoms frequently associated with rotator cuff tendonitis and tears are pain at the site along the tuberosity, night pain, exacerbation of the symptoms with lying on that shoulder at night, pain along the lateral aspect of the arm toward the insertion of the deltoid, and pain with overhead activities. A painful arc is present, and sometimes a drop arm test (pain on lowering the arm causing the individual to drop the arm rapidly) is noted. Manual strength testing can be done to isolate the supraspinatus, performed along the plane of the scapula (about 30° anterior to the frontal plane) with the arm internally rotated. Significant weakness will be noted if there is a full-thickness tear, and mild or no weakness is noted with partial tears, secondary to muscular compensation.

### Labral Tears

People with labral tears often report a history of trauma or falling on an outstretched arm. The pain is typically over

the anterior shoulder, and clicking is sometimes noted with abduction and external rotation. A clunk test may be positive with translation of the humerus over the edge of the labrum and may indicate instability of the shoulder or a labral tear. O'Brien's test loads the anterior labrum with the arm extended at the elbow, flexed and internally rotated at the shoulder in the Neer's position. It is then brought into adduction and a positive finding is noted with pain as the arm crosses the midline. Sensitivity of the O'Brien's test appears to be limited in isolation (approximately 63%); however, in combination with other tests, the sensitivity is better (45). One study revealed a 90% sensitivity of the O'Brien's test, and compression test and apprehension tests were all positive. In isolation, the most sensitive and specific test for labral tears appears to be the biceps load test II described by Kim et al. (44). The test is performed in the supine position, and the arm is elevated to 120 degrees and externally rotated to its maximal point, with the elbow in the 90 degrees flexion and the forearm in the supinated position. The patient is asked to flex the elbow while resisting the elbow flexion by the examiner. The test is considered positive if the patient complains of pain during the resisted elbow flexion. The test is negative if pain is not elicited or if the pre-existing pain during the elevation and external rotation of the arm is unchanged or diminished by the resisted elbow flexion. Diagnostic testing with an MRI may reveal a superior labrum anterior posterior (SLAP) lesion and signifies the direction of the tear. MRI arthrogram increases the sensitivity for finding a labral tear and is the test of choice if a labral tear is suspected.

### Adhesive Capsulitis or Frozen Shoulder

The pathophysiology of the frozen shoulder can be either idiopathic or associated with internal derangement such as trauma, tendonitis, and tears. Prolonged immobilization following one of these injuries is a significant risk factor. However, a frozen shoulder can occur in the absence of these diagnoses. Middle-age women and diabetic patients appear to be at a higher risk for spontaneous idiopathic adhesive capsulitis. The loss of range is multiplanar, with external rotation and abduction being the most affected. Clinically, the diagnosis should be suspected with progressive loss of range and diffuse pain despite conservative treatment measures. The syndrome is typically painful to treat and has a natural recovery that can be prolonged lasting up to 2 years. Early intervention may help with range in the pain-free zone (Codman's or pendulum exercises), joint mobilization with or without ultrasound, and a non-steroidal anti-inflammatory drug (NSAID) trial (Fig. 35-5). An intra-articular or subacromial injection of anesthetic and steroid may help (46). In addition, oral steroids may play a role in the acute management of adhesive capsulitis. According to Buchbinder and the Cochrane reviews, oral steroids provide significant short-term benefits in pain, range of movement of the shoulder, and function in adhesive capsulitis but the effect may not be maintained beyond 6 weeks (47). Distention of the capsule can be attempted but requires larger volumes to be injected (25 to 35 mL is the typical joint capacity). Initial infusion of lidocaine (3 to 5 mL) may make distention easier

**FIGURE 35-5.** Codman's exercise.

and less painful. Manipulation under anesthesia can be done but is generally a treatment of last resort.

### Neurovascular Compromise

#### *Plexus Injury*

Plexus injuries typically occur as a result of traction-type injuries. Sports-related injuries to the plexus are typically neuropraxic and have a good prognosis. There is some controversy regarding whether some of these neuropraxic injuries occur at the nerve root or plexus level. They are most commonly seen in football, wrestling, and hockey. These injuries are commonly referred to as “stingers” or “burners” and usually affect the upper part of the plexus. Weakness may last minutes. More direct trauma may result in a more severe injury to part or all of the plexus, and prolonged weakness may occur. Avulsion injuries, which are usually traumatic and require significant force, are associated with a poor prognosis.

#### *Axillary Nerve*

The axillary nerve is derived from the fifth and sixth cervical roots. It arises from the posterior cord of the brachial plexus. It courses in front of the subscapularis muscle and passes along the lower part of the capsule along with the posterior circumflex vessels. The nerve then travels through the quadrangular space. This space is bordered by the teres major inferiorly, the long head of the triceps medially, the neck of the humerus laterally, and the subscapularis and teres minor superiorly. This nerve is at greatest risk with dislocations of the shoulder and fracture of the surgical neck of the humerus. Testing for the sensory branch can aid in the evaluation for dislocation to detect nerve involvement. The sensation along the lateral aspect of the shoulder is innervated by the axillary nerve. This area of sensation can also be assessed after the dislocation is reduced to evaluate possible nerve involvement. Prognosis is good unless there has been extensive damage to the nerve, and recovery can take 6 to 12 months.

#### *Suprascapular Nerve*

The suprascapular nerve typically arises from the upper trunk of the brachial plexus. It runs along the middle scalene and under the trapezius. It passes over the superior aspect of the scapula along with the artery and vein and rests in the suprascapular notch. These structures are frequently held in place by a transverse ligament. This ligament may be ossified, therefore creating a foramen. The nerve then sends a branch to the supraspinatus muscle and wraps around the spinous process of the scapula at the supraglenoid notch before innervating the infraspinatus. This nerve is sensitive to entrapment at the notch and along the spine of the scapula. These syndromes are more commonly seen in throwing athletes, volleyball players, weight lifters, swimmers, and martial arts participants. Symptoms may include diffuse shoulder pain, impingement, weakness, atrophy, or scapular dysfunction. Electrodiagnostic studies may be helpful in the diagnosis.

#### *Long Thoracic Nerve*

The long thoracic nerve arises from the roots at C5, C6, C7, and C8. It passes along the base of the neck and along the inside of the serratus anterior. The serratus is essential for stabilizing the scapula and maintaining contact of the scapula with the thorax. It assists in protraction and upward rotation of the scapula. The nerve can be injured by either a direct blow to the neck or thorax or by repetitive and prolonged pressure at the base of the neck. This can be seen with backpacks or briefcases being carried on one shoulder. Patients typically complain of pain in the neck and shoulder region and weakness or heaviness with overhead activities. Physical findings reveal scapular winging of the inferior medial border with resisted protraction. Recovery is generally good because of the multiple nerve roots contributing to the nerve.

#### **Thoracic Outlet and Vascular Impingement**

Thoracic outlet is a controversial diagnosis. Its presence is thought to result from neurologic or vascular compromise of the structures at the base of the neck as they pass into the upper extremity. Entrapment may be noted at the scalene muscles where the trunk of the plexus passes through the muscle, along the first rib in the subclavicular space, or in the infraclavicular space along the coracoid and the pectoralis minor. The symptoms may be vague arm pain, numbness and tingling usually along the medial aspect of the arm, pain along the neck and shoulder region, weakness that is diffuse and does not follow a nerve root distribution, and muscle spasms. Provocative testing includes Adson's maneuver, which is positive when there is a drop in pulse palpated distally while the head is rotated to the involved side, resulting in contraction of the scalenes. Roos' maneuver, for more functional induction of symptoms, demonstrates increased vascular demand of the arms in an overhead position (see Table 35-6). A positive test is noted with reproduction of symptoms. Although this diagnosis is controversial, the treatment of the symptoms is rehab based. The exercise prescription for treatment of the neurogenic

symptoms is usually focused on myofascial release, stretching of the scalenes and pectoralis muscles, mobilization of the first rib, and postural exercises in addition to the general guidelines for shoulder rehabilitation. Cervical x-rays can be obtained to assess the presence of a cervical rib, which can contribute to the development of this syndrome. Electrodiagnostic studies may help to rule out other entrapment neuropathies and to support this clinical diagnosis.

### General Principles of Shoulder Rehabilitation

There are two general types of muscle coupling that occurs in the shoulder. One is the co-activation of muscles that allows for control of the extremity through a range. Examples of this type of coupling would be the upper trapezius, lower trapezius, and serratus for the rotation of the scapula. The second type is agonist/antagonist activity that allows for the transfer of forces. There is inhibition of the antagonist group of muscles with contraction or activation of the agonist group. Examples of this type include the pectoralis and latissimus muscles versus the infraspinatus and deltoid for control of internal rotation.

Nonoperative rehabilitation of the shoulder uses these principles for progression of an exercise program. Muscular substitution and inhibition particularly of the serratus anterior and upper trapezius muscles may lead to scapulothoracic dysfunction. In addition, position and movement of the scapula (with measurements of the “scapular slide”) will illustrate shoulder dysfunction, often seen early in shoulder injuries (48–50). Scapular motion may be restored with “scapular clock” exercises and include elevation, depression, protraction, and retraction. Scapular elevation/depression coupling utilizes trapezius, levator scapula, and rhomboids. Scapular protraction/retraction coupling is accomplished with rhomboids, mid trapezius, serratus, and pectoralis. Establishing good scapular position is essential for proceeding with a progressive exercise program.

Once scapular kinetics has been restored, glenohumeral range can be advanced and a progressive strengthening program should be prescribed. Strengthening of the scapular muscles, including the middle and lower trapezius, rhomboids, and serratus anterior, can be accomplished with either open- or closed-chain exercises. Open-chain exercises are more common but produce more shear forces along the joint. Frequently, these exercises are done with resistance. They help to facilitate scapulothoracic and glenohumeral control. Closed-chain exercises have less tensile stress along the capsular ligaments. They can be initiated with axial loading on a stable surface such as a table or an unstable surface such as a ball. They should be started with the arm in a pain-free position, typically slightly flexed with the trunk leaning on the arm (Fig. 35-6). This can then be advanced to loading the arm in an upright position on a wall with the arm either flexed or abducted. Strengthening of the rotator cuff may follow scapular stabilization and may focus on particular deficits noted within the cuff (Figs. 35-7 and 35-8).

**FIGURE 35-6.** Scapular stabilization.

Eventually, pyelometrics should be added to the exercise regimen. Most sporting activities require plyometric use of a muscle with eccentric loading just before concentric forceful contractions. Because this activity is seen in many shoulder functions, such as throwing, golf, racquetball, and baseball bat swings, it is essential to advance the athlete's program to include this in order to prevent reinjury. Medicine ball work with a rebounder will reproduce this type of exercise. Other examples are dynamic challenges that can be applied by a therapist in a stable position such as a tripod.

Rehabilitation of the shoulder should encompass a functional assessment of how the shoulder interacts and reacts with the rest of the body. Treatment may need to extend beyond the shoulder area. The legs are the foundation and are required for stability as well as to initiate the translation of energy from the larger muscles of the trunk to the shoulder girdle and eventually to the arm. There are several key points in the rehabilitation of the shoulder of a throwing athlete.

**FIGURE 35-7.** Isometric shoulder abduction strengthening.

**FIGURE 35-8.** Concentric shoulder adduction strengthening.

It should start with pelvic control over the planted leg, effective hip and trunk extension, scapular control (especially retraction), and normal glenohumeral rotation. Definition and use of the kinetic chain in the principles of rehabilitation are essential for an optimal outcome. Examination of the patient's posture, spinal alignment, and proximal hip strength should be included in the initial assessment for a patient with shoulder dysfunction.

Postoperative rehabilitation of the shoulder follows the same general guidelines. Immediate postoperative care includes aggressive treatment of pain, swelling, and range if and when the patient has been released to move the joint. Most surgeries for labral or capsular repair can begin with the range of motion early and progress to isometric exercises within the first few weeks. Isometrics are not allowed in rotator cuff repairs in the early phases of rehabilitation. These can be introduced usually at the 6-week postoperative period. Progression of the exercise occurs when the range of motion is 65% to 70% of the opposite side. The exercise protocols described by Kibler (51) include diagonal plane proprioceptive neuromuscular facilitation (PNF) exercises for scapular and glenohumeral motion in this phase of rehabilitation. In addition, closed-kinetic chain exercises are used to progress scapular retraction and depression. Once normal patterns are noted, strength can progress to open-kinetic chain exercises, pylonometrics, and trunk or core stabilization.

## SOFT-TISSUE INJURIES OF THE ELBOW

Soft-tissue injuries adjacent to the elbow are relatively common. Proper biomechanical functioning of the elbow is critical to ensure coordinated movement patterns and force transmission throughout the upper extremity. Assessment of the elbow likewise requires a functional understanding of the distal and proximal components in the upper extremity kinetic chain. In the context of soft-tissue elbow injuries, it is not unusual to

observe motion restriction due to joint contracture and musculotendinous shortening or weakness involving the shoulder, cervical spine, wrist, and digits. The success of rehabilitation is often based on normalizing function throughout the involved extremity.

The elbow joint is structurally complex. Although commonly referred to as a hinged joint, various articulations contribute to its dynamic movement. The ulnar-humeral joint is the primary articulation and contributes greatly to joint stability. It is a typical, single-axis, hinged joint allowing for 150 degrees of flexion. A few degrees of hyperextension is often seen, primarily in women, related to relative ligamentous laxity. The radiohumeral and proximal radioulnar articulations allow for axial rotation and can be considered pivot-type joints (52). Up to 75 degrees of forearm pronation and 85 degrees of supination are conveyed through these articulations. The radial and ulnar collateral ligaments, olecranon fossa, and anterior joint capsule act as the main static stabilizers of the elbow. Dynamic stability is conveyed through neuromuscular control about the elbow, with the biceps, triceps, pronator teres, and supinator providing the main stabilizing function. The radial, median, and ulnar nerves all become relatively accessible around the elbow and are susceptible to injury through direct trauma, repetitive overuse, compressive forces, or entrapment. These syndromes are often overlooked in the context of chronic elbow pain.

## Lateral Epicondylitis

Lateral epicondylitis is the most common presentation of lateral elbow pain. The annual incidence of the disorder is between 1% and 3% in the general population (53–55). Although often referred to as tennis elbow, 95% of reported cases occur in individuals other than tennis players. It is more frequently seen in occupations requiring repetitive upper extremity activities and particularly those involving computer use, heavy lifting, forceful forearm pronation and supination, and repetitive vibration. In athletics, racquet sports are most commonly associated with lateral epicondylitis; however, the injury is also seen in golf, baseball, and swimming (52,56). In tennis, the incidence appears to be between 30% and 40%. In general, tennis players with symptoms are older, play more frequently, and tend to be more skilled (57,58). This lends support to the mechanism of injury being one of repetitive overuse.

The clinical presentation of lateral epicondylitis is often clear (59,60). Most patients present with localized tenderness over the common forearm extensor tendon insertion at the lateral epicondyle, often extending into the extensor mass. Less commonly, there is discomfort over the radiohumeral joint and annular ligament. Pain is generally reproduced with resisted wrist and middle finger extension and with gripping activities. Passive wrist flexion with elbow extension often generates symptoms. Flexibility and strength deficits are often seen in the wrist extensor and posterior shoulder muscles.

The differential diagnosis of lateral epicondylitis is most relevant in the context of chronic, nonresponsive symptoms

**TABLE 35.7** Differential Diagnosis of Lateral Elbow Pain

Articular	Radiohumeral joint disease
	Radioulnar joint disease
	Periostitis
	Fibrillation of the radial head
	Ectopic calcification
	Panner's osteochondrosis
Soft tissue	Radiohumeral bursitis
	Annular and lateral ligament sprains
	Rupture of the common extensor origin
	Myofascial pain syndrome
Neurologic	Radial tunnel syndrome
	Posterior interosseous nerve compression
	Cervical radiculopathy
	Carpal tunnel syndrome

(12,43,61–63) (Table 35-7). Other soft-tissue considerations include radiohumeral bursitis, annular or lateral ligament strains, impingement of the synovial fringe, and myofascial strain involving the extensor forearm muscles. Neurologic considerations include cervical radiculopathy, radial tunnel syndrome, entrapment of the posterior interosseus nerve, and carpal tunnel syndrome. Radiocapitellar and proximal radioulnar arthritis are not uncommon in older adults. In the skeletally immature, Panner's disease, involving fragmentation of the capitellum, can be observed.

The site of pathology in most cases involves the insertion of the extensor carpi radialis brevis and less commonly the extensor carpi radialis longus and anterior extensor communis tendons. Due to repetitive overuse of the extensor forearm muscles, microscopic failure at the enthesis has been described. Pathologic findings have included mucinoid degeneration and granulation tissue in the subtendinous space. Nirschl (61) has reported extensively on the topic and proposes a theory that repetitive overuse is likely to cause vascular compromise resulting in anoxia and angiofibroblastic hyperplasia. These pathologic changes in the tendon have been defined as tendinosis (8).

The treatment of lateral epicondylitis follows the same principles for soft-tissue rehabilitation: control of inflammation, promotion of healing, reduction of abusive forces, and improvement of soft-tissue flexibility, strength, and endurance. In the context of acute injuries, resting the involved extremity and avoiding activities that reproduce symptoms are critical. Occasionally, a wrist cock-up splint may be necessary. NSAIDs and cryotherapy are useful in the acute phase. Therapeutic modalities are often administered to relieve pain and inflammation and possibly promote soft-tissue healing. The most common applications include cryotherapy, high-voltage galvanic stimulation, transcutaneous electrical nerve stimulation (TENS), ultrasound, phonophoresis, and iontophoresis (64–66). Acupuncture has been used successfully to

treat soft-tissue injuries (67–69). Although the mechanisms of action remain unsubstantiated, acupuncture likely has both analgesic and anti-inflammatory effects. The literature also remains inconclusive with respect to the clinical efficacy of many of the therapeutic modalities. Klaiman et al. (64) compared phonophoresis, using a corticosteroid gel, to ultrasound in a double-blinded design in a variety of soft-tissue conditions, including lateral epicondylitis. Although both modalities had a positive impact in terms of pain reduction and pressure tolerance at the site of maximal tenderness, there was no significant difference between the two therapies. Used conscientiously, however, in the initial stages of therapy or in the context of an acute exacerbation of symptoms, modalities may facilitate rehabilitation and allow the patient to advance to a more active program.

Corticosteroid injections are most appropriately used after failure of more conservative therapies or if acute symptoms are impeding other rehabilitation strategies (70). Intratendinous injections should be avoided, activity should be restricted for at least 7 to 10 days after the procedure, and patients should be well informed of the potential side effects, including skin depigmentation and atrophy, structural weakness, and in rare circumstances, tendon rupture. Injections can be repeated at monthly intervals but not more than three times in a year.

Therapeutic exercise is a necessary and critical component of soft-tissue rehabilitation (71–73). The injured site must be prepared to accept the demands of daily functional activities; otherwise, reinjury is likely to occur. Soft-tissue manipulation is often a valuable technique to improve tissue extensibility and promote tendon healing. Progressive loading of the wrist extensors is initially performed with passive stretching, advancing to progressive resistance training as the musculotendinous unit is able to accept greater demands without an increase in pain (Figs. 35-9 and 35-10). Strengthening is generally initiated with isometrics, advancing to concentric and ultimately

**FIGURE 35-9.** Passive wrist extensor stretching.

**FIGURE 35-10.** Passive wrist flexor stretching.

eccentric exercises (74). The emphasis is on the wrist extensors, flexors, and forearm supination and pronation (Figs. 35-11 to 35-14). It is also important to identify structural deficits in the kinetic chain extending from the cervical spine to the distal extremity. Weakness in the shoulder external rotators and inflexibility in the internal rotators should be identified and corrected. Aerobic conditioning should be maintained during the course of rehabilitation. This likely has a positive impact on soft-tissue healing.

Returning to sport or occupation requires that abusive forces be modified and activity specific exercises initiated. Factors pertaining to equipment and training are well recognized

**FIGURE 35-11.** Concentric wrist extensor strengthening.

**FIGURE 35-12.** Concentric wrist flexor strengthening.

as contributors to overuse injuries in sports. Poor backhand stroke mechanics in tennis, for example, have been associated with lateral epicondylitis. Corrective strategies in tennis have included switching to a two-handed backhand, using the largest comfortable grip, lowering string tension below 55 lb, switching to a more flexible and lightweight frame, playing with a softer ball, and wearing a counterforce forearm brace (60). The counterforce brace is believed to decrease the force of contraction from the forearm extensors and redistribute the force distal to the insertion at the lateral epicondyle (75,76). Injuries in the workplace necessitate a detailed ergonomic evaluation. Workstation modifications, education, and postural retraining

**FIGURE 35-13.** Concentric forearm supination strengthening.

**FIGURE 35-14.** Concentric forearm pronator strengthening.

are important interventions. A graded return to sport reduces the likelihood of reinjury. Tennis players are advised to begin hitting forehand strokes, advancing to the backhand and volley provided symptoms remain under control.

Surgery is generally reserved for chronic conditions that are unresponsive to conservative management and are associated with significant limitations in functional performance. The approach most commonly involves debridement of degenerative granulation tissue adjacent to the extensor carpi radialis brevis insertion and partial release of the common extensor aponeurosis (77,78). Postoperative rehabilitation employs the principles previously discussed and often requires 4 to 6 months before resumption of full activity.

### Medial Epicondylitis

Overuse injuries of the medial elbow typically involve the musculotendinous structures of the forearm flexor and pronator group, particularly the flexor communis and pronator teres (52,56,79). It is commonly seen in the throwing athlete as well as in racquet sports and particularly among more competitive players. Tennis players who use a topspin forehand and serve seem to be the most susceptible to medial elbow pain. Golfer's elbow refers to the same clinical syndrome. Patients complain of localized pain at the medial elbow with occasional radiation into the forearm. The symptoms are typically reproduced with resisted wrist flexion and forearm pronation as well as passive wrist extension and supination. In chronic situations, soft-tissue contractures may develop with loss of full elbow extension and supination.

The differential diagnosis of medial elbow pain includes medial collateral ligament sprain, muscular strain of the forearm flexors or pronator teres, anterior interosseous nerve entrapment (pronator teres syndrome), cervical radiculopathy, and thoracic outlet syndrome. Pain reproduction with a valgus stress while the elbow is extended 20 degrees is suggestive of ulnar collateral ligament sprain. This is more commonly seen in the throwing athlete and in severe cases may

be associated with a triad including ulnar collateral ligament strain, posteromedial capsuloligamentous strain, and ulnar neuropathy. Localized weakness in the flexor pollicis longus, the flexor digitorum profundus to the index and middle fingers, and the quadratus lumborum, in the absence of sensory deficits, suggests entrapment of the anterior interosseous nerve.

The treatment protocol for medial epicondylitis is similar to that already described for lateral epicondylitis. Managing pain and restoring full, pain-free range of motion at the elbow is necessary before initiating strengthening. Restriction in shoulder internal rotation should also be addressed. Resistance training focuses on the wrist flexors and pronator teres, advancing to eccentric training as symptoms permit. Counterforce bracing may assist in redistributing forces distal to the medial elbow and help to facilitate rehabilitation. Corticosteroid injections should be used with caution around the medial elbow because of the proximity of the ulnar nerve. Activity and sport-specific training focuses on biomechanical adaptations that may predispose to injury. In tennis, the athlete may be encouraged to hit more of a flat serve and use less wrist snap in the forehand stroke. Similarly, the golfer may be encouraged to use a larger and looser grip, to strike the ground less forcefully, and improve trunk rotation. Surgery is pursued only for intractable cases.

### Olecranon Bursitis

The location of the olecranon bursa, being superficial to the triceps insertion and olecranon, makes it susceptible to injury from acute trauma and repetitive friction. In sports, it is more commonly seen in wrestling, weight lifting, and gymnastics. It is also observed in skateboarders and rollerbladers who do not wear elbow protection. The differential diagnosis includes posterior elbow impingement syndrome, triceps tendinitis, and fracture of the olecranon. Patients with systemic arthropathies often develop bursal reactions but rarely is the elbow involved alone. Patients with acute olecranon bursitis present with pain and swelling, normal elbow range of motion, and pain reproduction with passive elbow flexion beyond 90 degrees. It is important to rule out an infected bursa and fracture of the olecranon or trochlea. Chronic conditions may not be painful, and the bursa often feels thickened and boggy. Treatment includes pressure relief over the elbow, cryotherapy, anti-inflammatory drugs, and compression, particularly in the acute phase. A suspected infected bursa should be aspirated and analyzed before instituting appropriate antibiotic therapy. Aspiration may also be indicated in a severely swollen sterile bursa, and in chronic conditions, surgical excision may be necessary.

### Triceps Tendinitis

Triceps tendinitis generally occurs as a result of repetitive overuse or extension overload at the elbow. The injury is seen in boxers, pitchers, weight lifters, bowlers, and gymnasts. The injury, associated with inflammation and microtrauma, typically occurs at the insertion of the triceps to the olecranon process. Pain is reproduced with resisted elbow extension and passive elbow

flexion with shoulder forward flexion. In the throwing athlete, loss of flexibility may be seen in elbow flexion and shoulder internal rotation. In atypical cases, patients will report a snapping sensation at the elbow caused by subluxation of the medial head of the triceps over the medial epicondyle. This is distinguished from subluxation of the ulnar nerve at the medial elbow owing to the absence of sensory symptoms in the hand.

The treatment of triceps tendinitis requires activity modification; therapeutic modalities including cryotherapy, ultrasound, or phonophoresis; electrical stimulation, and soft-tissue manipulation. Therapeutic exercise emphasizes flexibility training through the kinetic chain with a focus on elbow flexion and shoulder flexion and internal rotation. Progressive resistance training and a graded return to activity are addressed, monitoring for any increase in symptoms. An orthosis, limiting full extension of the elbow, may be useful during this period of reconditioning.

## PERIPHERAL NERVE SYNDROMES

### Ulnar Neuropathy

The ulnar nerve, originating from the medial cord of the brachial plexus, is well protected in the upper arm behind the medial head of the triceps and, except for associated trauma in the presence of humeral shaft fractures, is relatively spared of injury in the upper arm. As the nerve emerges into the cubital tunnel, bordered by the medial epicondyle, olecranon, medial collateral ligament, and aponeurosis of the flexor carpi ulnaris, it becomes more superficial and susceptible to trauma and repetitive overuse. In cubital tunnel syndrome, the nerve is particularly vulnerable as it passes through the fibrous arch connecting the two heads of the flexor carpi ulnaris (80–82). The arch is taut with elbow flexion and situations of repetitive or sustained elbow flexion increase the risk of nerve irritation and injury.

The patient with cubital tunnel syndrome may present with vague elbow pain but typically reports pain, paresthesias, and numbness in the fifth and ulnar aspect of the fourth fingers. Even though the branches of the ulnar nerve to the flexor carpi ulnaris and flexor digitorum profundus originate below the cubital tunnel, these muscles are often spared in cubital tunnel syndrome, as the nerve fascicles to the intrinsic hand muscles tend to be most affected. Percussion at the medial elbow (Tinel's sign) will often reproduce symptoms in the hand. Maintaining the elbow in a fully flexed position for up to 5 minutes (elbow flexion test) may also induce symptoms. Patients can demonstrate impaired light touch sensation and two-point discrimination along the fifth and ulnar aspect of the fourth fingers. In more advanced cases, muscle atrophy can be seen in the intrinsic hand muscles and particularly the first dorsal interosseous. Weakness in the adductor pollicis can be demonstrated by a positive Froment's sign, in which patients will compensate with the flexor pollicis longus when attempting to squeeze a piece of paper between the thumb and the index finger.

Electrodiagnostic studies are useful in confirming ulnar neuropathy at the elbow in addition to ruling out other diagnostic considerations including cervical radiculopathy, plexopathy, and distal entrapment neuropathies at the wrist. Imaging of the elbow should also be considered to rule out a compressive lesion. Clinical examination will assist in ruling out other sources of soft-tissue pain at the medial elbow including medial epicondylitis, ulnar collateral ligament strain, and olecranon bursitis.

Mild cases of ulnar neuropathy can be effectively managed with anti-inflammatory medication, curtailing activities that result in direct pressure or frictional stress to the medial elbow, and if necessary, an elbow pad. Surgical management, consisting of decompression and transposition of the ulnar nerve, is generally reserved for more severe cases manifesting with persistent pain and neurological compromise.

### Radial Neuropathy

Above the elbow, the radial nerve is most susceptible to injury as a result of compression at the level of the spiral groove or following mid humerus shaft fractures. In both instances, the triceps muscle is generally spared, and motor/sensory deficits can be observed in a predictable distribution below the level of the lesion. As the radial nerve emerges under the extensor carpi radialis longus at the lateral elbow, it divides into the superficial radial and posterior interosseous nerves. Radial tunnel syndrome, or compression of the posterior interosseous nerve, has been best described as the nerve that enters through a fibrous band (arcade of Froshe) between the two heads of the supinator muscle (62,63,83,84). This is generally believed to be a repetitive motion disorder, involving extension of the elbow and pronation of the forearm, and should be considered as a cause of persistent lateral elbow pain, although diffuse forearm pain is common. While patients will often demonstrate tenderness at the origin of the common extensor tendon, maximal pain can be elicited with palpation over the supinator, and unlike tennis elbow, resisted forearm supination is more painful than resisted wrist and middle finger extension. Sensory symptoms should be absent as the posterior interosseous nerve is a pure motor nerve and weakness in wrist and finger extension can be observed, particularly in chronic cases.

Electrodiagnostic studies are commonly unrevealing in radial tunnel syndrome. Radial motor conduction slowing may be observed across the lateral elbow, and electromyography may reveal denervation and polyphasic motor unit potentials in the distribution of the nerve, generally sparing the extensor carpi radialis longus and brevis, as well as the supinator. Diagnostic lidocaine injections can also be used to attempt to distinguish lateral epicondylitis from radial tunnel syndrome. Surgical exploration and decompression of the nerve should be reserved for resistant cases unresponsive to conservative strategies including physical therapy, injection therapy, and acupuncture.

### Median Neuropathy

The median nerve is also uncommonly injured in the upper arm, generally susceptible in cases of blunt trauma or fracture.

As the nerve emerges along the distal medial humerus, it passes under the ligament of Struthers, a fibrous band that attaches to an anomalous supracondylar spur. This represents a potential, albeit, rare site of median nerve compression. Lesions at this level may be associated with pain at the medial elbow, distal sensory symptoms in the distribution of the median nerve, and weakness below the level of the lesion, including the pronator teres. This feature often distinguishes it from pronator teres syndrome, in which median nerve entrapment occurs as the nerve penetrates the two heads of the pronator teres and is compressed against the flexor digitorum sublimis (85,86). Since the median nerve branches to the pronator teres arise proximal to the muscle, weakness in forearm pronation is not typically observed.

The anterior interosseous nerve, a pure motor branch of the median nerve, emerges below the two heads of the pronator teres and may also be susceptible to injury. Compression of the nerve against accessory muscle involving the flexor pollicis longus and flexor digitorum superficialis has been reported. Distinguishing clinical features include the absence of sensory symptoms, preservation of forearm pronation strength, and weakness in the flexor pollicis longus, flexor digitorum profundus (digits 1 and 2), and pronator quadratus. The loss of tip-tip pinch between the index finger and the thumb (pinch sign) demonstrates this pattern of weakness. Nerve conduction studies are typically normal but may demonstrate prolonged latency of the anterior interosseous nerve in the forearm. Electromyography may be helpful in diagnosis, particularly distinguishing pronator teres and anterior interosseous nerve syndromes. As previously discussed, failure of conservative management may necessitate surgical decompression. Distal entrapment of the median nerve at the wrist will not be discussed here.

# Cumulative Trauma Disorders

Cumulative trauma disorders (CTDs) are injuries to the nervous and/or musculoskeletal system attributed to repetitive physical tasks, poor sustained posture/biomechanics, vibrations, and/or repetitive forceful exertions (1). It has also been called repetitive strain injury, overuse injury syndrome, cumulative movement disorder, and repetitive motion injury. CTD is an umbrella term that includes multiple specific diagnoses and nonspecific conditions affecting primarily the upper limbs, shoulder, neck, and lower back. Furthermore, within each of these body regions, there can be multiple types of CTDs that involve pathology of the tendons, joints, muscles, or nerves. Among the most common CTDs are lumbar back pain, carpal tunnel syndrome (CTS), epicondylitis, neck pain, and de Quervain's tenosynovitis. Although the workplace is the most common setting for development of CTD, these disorders can arise in any setting with prolonged exposure to the aforementioned mechanical stressors.

The mainstay of CTD management involves ergonomic interventions to correct underlying postural and mechanical causes. Treating symptoms without modifying the workplace is the primary reason for recurrence of CTD and magnifies the overall economic burden caused by these disorders. In addition to ergonomic interventions, treatment can include physical therapy, orthotic devices, anti-inflammatory medication, muscle relaxants, pain medications, steroid injections, and surgical interventions in select cases. Psychosocial factors play a significant role in disability resulting from CTD and must be addressed as well.

## EPIDEMIOLOGY AND ECONOMIC COSTS

According to the U.S. Bureau of Labor Statistics, there were 357,160 total recorded cases of musculoskeletal disorders in 2006 that resulted in time away from work. CTDs account for approximately 56% to 65% of all occupational injuries (2). There are several diagnoses that are due to cumulative trauma, with the most common being low back pain (LBP), CTS, and neck/shoulder pain. Repetitive motion injuries as a group had a median of 19 missed workdays (BLS, 2006; <http://www.bls.gov/>). Based upon these numbers, CTDs are commonplace and constitute a large portion of occupational injuries.

The economic costs of CTDs are enormous. Total U.S. annual cost estimates have ranged from \$13 to \$20 billion (3). Estimating cost is a challenge since CTDs can encompass

varying diagnostic entities from one study to the next. Additionally, it can be difficult to attribute the cause of workplace injuries to repetitive stresses versus acute overexertion over a brief time period since there are no clear cut temporal definitions currently used in the literature.

## PATHOPHYSIOLOGY

Although many hypotheses have been put forth, the pathophysiology of CTDs is not completely understood. Cumulative biomechanical stresses can result in tissue alteration in tendons, muscles, joints, and nerves over time. In soft tissues, damage is marked by inflammation, collagen deposition, and tissue contraction, which can in turn lead to pain or loss of motion. One hypothesis to explain the origins of myalgia is that prolonged muscle contractions lead to decreased local blood flow, deoxygenation, and metabolite buildup that manifest as muscle fatigue and soreness (4). The mechanism for tendon-related disorders may be related to inflammation and hypoxia. It has been demonstrated that repeated mechanical stresses release prostaglandin E2 (PGE2) from human fibroblasts *in vivo* (5). Exposure of rabbit patellar tendons to PGE2 resulted in degenerative changes. Therefore, tendon pathology may result from prolonged or recurring inflammation. Another possible precipitant is hypovascularity, which may predispose tendons to hypoxic degeneration and subsequent tendinopathy. Regardless of cause, tendinopathies have been shown to have disordered collagen arrangement and increased proteoglycan ground substance (6). The most common site of overuse injury is the osteotendinous junction (7). When referring to the general term tendinopathy, it is important to make the distinction between tendonitis, an acute inflammatory process, versus tendinosis, a chronic, degenerative process of the tendon.

## PSYCHOSOCIAL

Several studies show that psychosocial factors contribute to disability in CTD, especially in cases involving cervical or lumbar spine pain. CTDs are costly to both employers and employees. They result not only in time lost from work but also in decreased productivity and poor employee morale, which in turn leads to further disability (8). Studies have identified job dissatisfaction (9,10) as a significant risk factor for the

development of LBP. One study analyzed industrial insurance data to demonstrate a positive correlation between low income and divorce with chronicity of LBP (11). Dersh et al. found that 56% of patients with occupational LBP had major depression, while 11% had an anxiety disorder (12).

Although less studied, there is evidence to suggest that psychosocial factors play an important role in the severity or chronicity of CTDs that are unrelated to spine pain. One study used patients' self-report of upper extremity symptoms to show a positive correlation between depression and severity of carpal tunnel, de Quervain's tenosynovitis, lateral elbow pain, and trigger finger (13). Another study found job strain to adversely affect successful return to employment in CTS patients (14).

The correlation between significant psychosocial stressors and disability from CTD introduces the question of which issue arises first. A recent epidemiologic study suggested that most patients with occupational LBP found that most psychiatric disorders appear only after the onset of work injury (15). Nonetheless, these factors have been shown in several pain conditions as contributing to chronicity even if they are a secondary process. Overall, there is increasing evidence that these issues should be addressed appropriately for optimal recovery. In evaluating new CTD patients, clinicians should screen for psychosocial factors and psychiatric comorbidities and consult relevant mental health practitioners if indicated.

## ERGONOMICS

According to the International Ergonomics Association Council of 2000, ergonomics is "the scientific discipline concerned with the understanding of interactions among humans and other elements of a system, and the profession that applies theory, principles, data and methods to design in order to optimize human well-being and overall system performance." It requires an understanding of human abilities and the limitations imposed by the work environment, machines, tools, and specific job tasks (4).

Several elements contribute to occupational CTD, including forceful exertions, repetition of a work task, awkward biomechanical postures, and vibration (1). The National Institute for Occupational Safety and Health (NIOSH), a division of the U.S. Department of Health, reviewed the epidemiological evidence for each of these physical work factors for the major CTD subtypes. A brief summary of these findings is presented below. It is important to note that many CTDs will involve a combination of these factors.

### Repetition or Prolonged Activities

Repetitiveness is commonly cited as an occupational factor leading to CTD of the upper extremity (8). It can be defined as cyclical or repeated motions requiring contraction of the same muscles to mobilize joints. The NIOSH conducted a 1997 review that found moderate evidence for repetition as a cause of work-related musculoskeletal disorders in neck and

shoulder pain, CTS, and hand/wrist tendonitis. It did not find sufficient evidence in LBP or epicondylitis (1).

### Forceful Exertions

There is epidemiologic evidence to support the role of forceful exertions in the workplace in contributing to neck, lumbar back, elbow, and hand/wrist pain. Ergonomic design plays a critical role as force requirements may increase based upon several factors including poor body mechanics, high torque or speed of power tools, and friction between objects and the worker (16).

### Posture

Improper postural mechanics during the performance of a task appears to play a significant role in the development of CTD, especially those involving the spine and upper extremities. Sustained wrist and forearm flexion-extension or radial-ulnar deviation may induce friction between tendons and adjacent anatomic surfaces. A good example of this is frequent radial deviation of the wrist and subsequent development of de Quervain's tenosynovitis.

### Vibration

Another frequently mentioned risk factor in CTD is vibration (17). Exposure to vibration occurs in a variety of contexts: using power tools, holding an object as it is processed in a machine (e.g., wood in a power saw), or using percussion tools (e.g., hammering a nail). Vibration has been implicated as the cause of Hand-Arm Vibration Syndrome (HAVS).

## CUMULATIVE TRAUMA DISORDERS

As the various CTDs of the upper extremity and spine are discussed, emphasis is placed on anatomy, pathophysiology, incidence, clinical diagnosis, and management. There are some common trends in CTDs. In general, the pathophysiologic mechanisms of these disorders are not completely understood. The evidence for cumulative trauma in the pathogenesis of these conditions is discussed, and summary is provided in Table 36-1. Diagnosis of these conditions is typically made primarily based upon clinical history and exam, with supportive studies such as imaging or electrodiagnosis used in equivocal cases. Table 36-2 provides a summary of specific exam maneuvers suggestive of a certain CTD. Management begins with relative rest and workplace modification including ergonomic interventions. Conservative treatments include nonsteroidal anti-inflammatory drugs (NSAIDs), therapeutic heat/cold, and physiotherapy consisting of stretching and strengthening of relevant muscle groups. Other modalities such as myofascial release, deep friction massage, transcutaneous electrical nerve stimulation (TENS), acupuncture, ultrasound, and iontophoresis are not well described in the literature. Steroid injections can be utilized in some conditions when the above treatments fail. Finally, surgery can be performed in refractory cases.

**TABLE 36.1** Evidence for Causal Relationship Between Cumulative Trauma and Various Neuromusculoskeletal Conditions

Condition	Level of Evidence
Spine	
Neck pain	II
Low back pain	I
Shoulder	
Rotator cuff tendinopathy	II
Impingement	IV
Bicipital tendinopathy	IV
Elbow	
Epicondylitis	II
Hand	
Trigger finger	II
de Quervain's tenosynovitis	II
Hand-arm vibration syndrome	I
Nerve entrapment syndromes	
Carpal tunnel syndrome	I
Cubital tunnel syndrome	II
Thoracic outlet syndrome	IV

Level of evidence grading: Because it is unethical to perform controlled trials exposing subjects to cumulative trauma, the following modified grading system is used:

I: Highly supportive evidence from well-designed cohort or cross-sectional studies.

II: Highly supportive evidence from well-designed case-control studies or moderately supportive evidence from cohort or cross-sectional studies.

III: Supportive evidence from case report(s) or series.

IV: Supportive expert opinion.

## Neck

The cervical spine is a complex structure consisting of eight individual motion segments, beginning with the articulation of the occiput on C1 (atlas) and ending with the articulation

between C7 and T1. Cervical nerve roots exit bilaterally through intervertebral foramen to innervate the myotomes and dermatomes of the head, neck, and arms. The cervical musculature controls head movement and provides stability. Pain in the neck area can arise from overwork of the musculature, impingement of cervical nerve roots, or degenerative arthritis of the spine. Neck pain is commonly encountered in jobs requiring prolonged posturing of the neck, forceful exertions, and highly repetitive tasks with static postural loads. Because major neck muscles extend to the shoulder or base of the skull, shoulder pain and headache are commonly associated. Tension neck syndrome involves persistently stiff neck muscles resulting in aching discomfort at the base of the neck, upper back, and suboccipital region.

Poor neck posture has been strongly associated with occupational neck pain and appears to be the most significant factor in work-related neck disorders. Specifically, prolonged neck flexion or extension in combination with arm elevation is problematic. Mayoux-Benhamou and Revel used electromyography (EMG) to demonstrate improved neck muscle efficiency with neutral head position as compared to the flexed or extended position (18). Other studies have found associations between forward head posture and headaches (19), overhead arm tasks and radiating neck pain (20), and simultaneous head extension and arm elevation with neck/shoulder pain (21). The literature has also identified certain occupations involving overhead work with a higher incidence of neck pain. Neck symptoms were reported in 62% of dental hygienists and 66% of sewing machine operators with more than 15 years of experience (22,23). Significant symptoms related to the neck have also been reported in dentists, meat carriers, miners, heavy labor workers, iron foundry workers, and civil servants (24).

Repetition and high exertional loads are important factors in neck pain as well. A cross-sectional study of 82 female assembly line workers who were exposed to repeated intermittent

**TABLE 36.2** Special Diagnostic Tests Associated with CTD

Cumulative Trauma Disorder	Diagnostic Test
Carpal tunnel syndrome	Phalen's: wrist flexion to 90 degree maintained for 60 s. Tinel's: tapping of median nerve at carpal tunnel.
Cubital tunnel syndrome	Tinel's: tapping of ulnar nerve at cubital tunnel in flexed elbow.
Thoracic outlet syndrome	Adson's: abduction and external rotation of the shoulder of affected side. Loss of radial pulse indicates positive test. Roo's: alternating finger extension and flexion to form a fist for 60 s while patient's shoulders are held in abduction and elbow in 90-degree flexion. Reproduction of paresthesias or inability to perform maneuver on affected side indicates positive test.
Impingement	Neer's: pain with full passive shoulder flexion. Hawkins': internal rotation and abduction of shoulder with elbow flexed at 90 degrees.
Supraspinatus tendinopathy	Empty can test: resistance to shoulder extension with the subject's elbow fully extended and the fist directed such that the thumb is pointing toward the ground.
Bicipital tendinopathy	Speed's: resisted shoulder flexion with the arm in supinated position and the elbow flexed at 15 degrees.
de Quervain's tenosynovitis	Finkelstein's: passive ulnar deviation of the hand with the thumb fully flexed in a closed fist.
Lateral epicondylitis	Cozen's: resistance of wrist extension and radial deviation with the subject's arm in pronated position.

neck flexion and shoulder abduction revealed an odd ratio (OR) of 4.6 for any neck/shoulder diagnosis and OR of 3.6 for diagnosis of neck tension syndrome (25). A smaller, but more quantitative, study measured trapezius activity on surface EMG in order to demonstrate that increased frequency of sustained, low muscle activity was positively correlated with neck discomfort in workers (26). For forceful exertions, the trapezius is the major muscle of the neck utilized to carry out work involving high forces. One longitudinal study found that workers with a reduced static trapezius load had less shoulder pain at 2-years follow-up (27). Another study found that postal workers, who carry heavy shoulder bags, consistently reported greater shoulder/neck disability compared to gas meter readers who perform a similar amount of walking as postal workers (28). This was the case after controlling for age, work years, and previous lifting work.

Management of neck pain involves avoiding prolonged static postures and introducing dynamic and varied work tasks (29). Exercise therapy for mechanical neck disorders has short-term benefits in terms of pain and function (30). Although no specific exercises can be clearly recommended over others based upon evidence, a reasonable regimen would include neck retraction exercises, stretching of the anterior shoulder capsule and pectoralis muscles, and strengthening of the trapezius and rhomboids. In general, treatments for neck pain arising from cumulative trauma have not been well studied, and management principles have been extrapolated from general mechanical neck pain studies. Pharmacotherapy can include NSAIDs, muscle relaxants, and opioids for severe pain. Manipulation alone is not helpful but may have benefit in conjunction with exercise therapy (31). There is moderate evidence for a lack of efficacy of botulinum toxin injections in chronic mechanical neck pain according to a recent systematic review (31). The therapeutic value of TENS, biofeedback, and acupuncture remain unclear. For further details regarding cervical spine pain, refer to Chapter 32.

## Shoulder

The shoulder is a complex structure that affords great mobility at the expense of stability. Its stability can be divided into static and dynamic components. Statically, the bony glenoid, cartilaginous labrum, glenohumeral ligaments, and joint capsule provide moderate stability. Dynamically, the rotator cuff muscles and biceps tendon function to assist with shoulder stability. The most frequent CTDs of the shoulder are rotator cuff tendinopathy (especially involving the supraspinatus), biceps tendinopathy, and shoulder impingement.

The rotator cuff consists of the supraspinatus, infraspinatus, subscapularis, and teres minor and resides in the subacromial space, which is defined by the acromion, subacromial bursa, and coracoacromial ligament above; the coracoid process at the medial border; and the humeral head below. The rotator cuff plays an especially important role in the case of overhead elevation of the arm, which requires tonic contraction to keep the humeral head anchored in the shallow glenoid fossa (32). This explains why rotator cuff tendinopathy

is particularly common in laborers who work with their arms overhead or athletes who throw repeatedly (7).

A disorder that often accompanies rotator cuff tendinopathy is impingement syndrome, in which there is progressive encroachment of the rotator cuff tendons in the subacromial space due to intrinsic or extrinsic sources (33). Intrinsic causes include trauma or degeneration of the rotator cuff with instability or laxity of the shoulder complex. The laxity results in cephalad migration of the humeral head resulting in impingement. Extrinsic causes include bony changes to the acromion, coracoid, acromioclavicular joint or greater tuberosity, cervical nerve root compression, and other systemic conditions, including rheumatic disorders. Acromial morphology (type I flat, type II curved, type III hooked) is another factor that can predispose one to impingement (34). Individuals with a hooked acromion are most likely to develop rotator cuff abnormalities. The positioning of the rotator cuff has also been reported as having a relationship to rotator cuff pathology. Rathbun and Macnab report the “wringing out” phenomenon, whereby a hypovascular region in the supraspinatus tendon is created when the arm is held in adduction (35). Overall, shoulder impingement, a mechanical compression process, often leads to rotator cuff tendinopathy, which can lead to further impingement.

The individual with rotator cuff tendinopathy or impingement syndrome will report pain deep within the shoulder or posteriorly, with referral to the deltoid muscle insertion region. There may also be loss of strength and motion secondary to the pain. The discomfort is worsened by activities at shoulder level or above. Pain will occasionally occur at night while resting on the involved shoulder, perhaps from a concomitant subacromial bursitis. On physical examination, a positive Hawkins’ or Neer’s sign is suggestive of impingement. Hawkins’ test involves passive internal rotation and abduction of the shoulder while the elbow is flexed at 90 degrees. Neer’s test involves forward shoulder flexion until the arm is overhead while simultaneously maintaining light pressure on the acromion. Other tests include diagnostic injection of local anesthetic into the subacromial space, which should provide temporary pain relief and improved ROM in these conditions. The differentiation of rotator cuff tendinopathy and impingement is often difficult. A helpful clinical maneuver to differentiate these conditions is to assess isometric strength testing of the rotator cuff muscles (i.e., resisted external rotation of shoulder or abduction), which should produce moderate to severe pain in rotator cuff tendonitis, but minimal discomfort in a pure impingement syndrome. Further evaluation can include imaging such as x-rays or MRI/MR arthrography, which may show narrowed subacromial space, calcified tendons, or partial tears.

Bicipital tendinopathy is another condition that can result from repetitive strain and overhead reaching. Patients typically complain of anterior shoulder pain localized to the region of the bicipital groove. On examination, a positive Yergason’s or Speed’s maneuver (36) along with pain during active elbow flexion may be important clues. Diagnostic injection with local anesthetic or MRI may confirm this clinical diagnosis. Since other shoulder pathology frequently occurs in concert, the

clinician should also investigate for rotator cuff tendinopathy, impingement, or shoulder instability.

There have been numerous studies illustrating the association between repetitive movements and/or exertional force and shoulder pathology. Chiang et al. found an OR of 1.6 (95% CI 1.1 to 2.5) among fish-processing workers' repetitive upper limb movement and shoulder girdle pain (37). Another cross-sectional study of fish industry workers revealed that repeated arm elevations and shoulder abductions as documented on videotape were significantly associated with shoulder and neck pain (25). Welch et al. noted a prevalence of 32% incidence of rotator cuff injury in sheet metal workers, with most occurring from overhead duct work (38). Other at-risk occupations for shoulder pain include electricians (39), garment workers (40), hospital workers (41), and construction workers (42). Herberts et al. reported 18% of shipyard welders and 16% of steel plate workers had rotator cuff pathology (especially supraspinatus tendonitis) (43). Overall, rotator cuff injury has been reported as the third most common diagnosis encountered in workers, accounting for 8.3% of cases (44).

In the industrial setting, treatment of shoulder impingement and tendinopathy emphasizes avoiding awkward postures and decreasing overhead work, especially tasks involving shoulder internal rotation. One study found that postural alterations could improve the range of shoulder motion at which pain was experienced, in spite of having no overall effect on pain intensity in symptomatic impingement patients (45). Acute interventions include NSAIDs, ice, and pain management. If persistent, corticosteroid injections into the subacromial space can be utilized. Range-of-motion exercises involving both the glenohumeral and scapulothoracic articulations will decrease the likelihood of asynchronous motion leading to impingement. Strengthening exercises should focus on the rotator cuff muscles and scapular stabilizers.

## Elbow Epicondylitis

The lateral and medial epicondyles serve as the origins of the musculature for the forearm and wrist. Lateral epicondylitis (also termed *tennis elbow*) and medial epicondylitis (also termed *golfer's elbow*) are overuse syndromes of these muscles. Of these two disorders, lateral epicondylitis is more common and usually involves the extensor carpi radialis brevis and less commonly the extensor carpi radialis longus, extensor digitorum communis, or extensor carpi ulnaris. Medial epicondylitis typically involves the pronator teres and flexors carpi radialis and ulnaris.

Epicondylitis begins as an inflammatory reaction within the tendinous origin and progresses to microtears that heal through fibrosis and granulation tissue production. It is common in both sports as well as in occupations such as gardening, dentistry, meat processing (46), cashiers, and carpentry. It is an overuse syndrome precipitated by repetitive contraction of the wrist flexors/extensors or pronators/supinators, such as in hand gripping, twisting or screwing motions, hammering, assembling small parts (47), or swinging sporting equipment. Any

contraction of muscle can be either concentric, which results in muscle shortening, or eccentric, which results in muscle lengthening. Between these two contractions, eccentric muscle overload results in higher muscle tension and appears to be more likely to cause injury than concentric contractions (48).

The diagnosis of epicondylitis is based on history and physical examination. Patients with lateral epicondylitis typically report focal lateral epicondylar pain, pain with resisted wrist extension and radial deviation, and possibly weakness of hand grip due to muscle fatigue and discomfort. Medial epicondylitis presents with focal pain at the medial epicondyle, pain with resisted wrist flexion and radial deviation, and possibly decreased hand grip strength. In both lateral and medial epicondylitis, there should be normal elbow range of motion; otherwise, elbow pathology should be investigated. In equivocal cases, further diagnostic workup may include local anesthetic injection or imaging. An anesthetic block in either the lateral or the medial epicondyle will confirm the diagnosis. MRI evaluation showing distinct signal intensity changes and contrast enhancement can be correlated with fibrovascular proliferation and fatty degeneration of the common extensor tendon. Minor signal intensity changes without contrast enhancement correlate with fibrosclerotic degeneration and intratendinous cartilage formation (49). MRI will also be helpful in distinguishing epicondylitis from other conditions such as stress fractures, ligament and tendon injury, and nerve entrapment (entrapment of the posterior interosseous nerve may mimic lateral epicondylitis) (50). Diagnostic ultrasound is an emerging diagnostic tool in epicondylitis that may also provide information about disease severity (51).

Treatment of epicondylitis begins with relative rest and ergonomic improvements in tool or sporting equipment design. Medical care for epicondylitis often begins with activity restriction, icing, and anti-inflammatory medication. In terms of anti-inflammatory medications, both oral and topical medications have shown short-term pain improvement (52). Prior to progressive strengthening exercise, the patient should work toward obtaining pain-free movements in wrist flexion/extension and pronation/supination. Strengthening regimens begin with light concentric exercises for all motions about the wrist and forearm, including grip strength. The program is then advanced to include eccentric exercises as well as more work-specific activities. In a small pilot study, an eccentric exercise program demonstrated significantly reduced symptoms compared with concentric strengthening in lateral epicondylar pain (53). Return to limited work activities can be attempted when strength is 80% of that in the noninvolved side. Work volume should not increase by more than 5% per day (54).

Studies involving local corticosteroids have yielded conflicting results. Many studies have shown improvement of symptoms in the acute period but no differences in outcomes at 1 year. One study actually found 1-year outcomes to be better in patients treated with physical therapy or a "wait and see" approach (55).

Use of a counterforce brace can reduce torque about the extensor digitorum brevis muscle and may be an effective

treatment option (56). A Cochrane review in 2001, however, found that no definitive conclusions could be drawn with regard to efficacy of orthotics in lateral epicondylitis (57).

There continues to be research on less traditional modalities such as acupuncture, shock wave therapy, deep tissue massage, and autologous blood injections. Fink et al. conducted a small randomized trial with acupuncture that resulted in decreased pain at 2 weeks from the start of treatment and improved arm function at 2 months compared with sham acupuncture (58). A 2004 review of six trials concluded that acupuncture is very effective in lateral epicondyle pain in the short term (59). There is limited evidence to support deep tissue massage as a treatment option. Gehlsen et al. demonstrated enlargement of fibroblasts in damaged tendons of rats following heavy-pressure soft-tissue mobilization (60). It is, therefore, implied that deep tissue massage can stimulate healing, although quality randomized control trials are lacking. Extracorporeal shock wave therapy (ESWT) has been used for over a decade as a conservative therapy for chronic lateral epicondylitis. However, a recent systematic review of ESWT found “platinum” level evidence of little to no benefit (61). There are a few studies suggesting the benefit of autologous blood injections in epicondylitis, but further research is needed to determine the efficacy of this treatment (62). Finally, surgery is a treatment of last resort, although there have been no controlled trials investigating its efficacy.

### Trigger Finger (Flexor Tenosynovitis)

The finger flexor tendons of the hand are enclosed by a synovial sheath that extends from the metacarpal bones to the distal interphalangeal (DIP) joints. There is a series of fibrous “pulleys” that tether the flexor tendons to the IP joints, allowing frictionless finger flexion. The pulleys are arranged in a series along the flexor surface of the digits, starting with the A-1 pulley at the metacarpophalangeal (MCP) joint area to the A-5 pulley at the volar plate of the DIP joint. The flexor tendons are surrounded by tenosynovium, which allows smooth movement underneath the pulleys during finger flexion and extension. In trigger finger, there is inflammation and thickening of the tenosynovium or pulleys, leading to tendon nodule formation. These changes compromise the normal smooth gliding motion of the tenosynovium under the pulleys and the involved digit may even become locked in a flexed position. Histologically, fibrocartilaginous metaplasia and synovial proliferation are noted in and about the tendon and pulley (63).

The pathophysiology of trigger finger is thought to be a multimodal process, involving a combination of degenerative changes, inflammation, local trauma, and heredity. Certain hand motions have been implicated. These include prolonged hand gripping especially with an excessively wide grip, use of pistol-gripped power tools that require frequent finger flexion, and repetitive flexion of the distal interphalangeal joint (DIP) with extension of the proximal interphalangeal joint (PIP) and metacarpophalangeal joints (MTP). Occupational trigger finger has been described in homemakers, manual laborers, sewing machine operators, welders, and processing plant workers (63,64). However, more recent studies have questioned the

work-related nature of this disorder, including a British study that suggested that the vast majority of cases are nonwork related (65).

The presenting symptoms of trigger finger vary from a slight clicking to occasional frank locking. “Triggering” refers to a catching of the tendon and occurs more commonly in flexion. Pain, if present, occurs with finger extension and is most pronounced at the site of the nodule or thickened pulley, which is typically at the MTP joint. On physical examination, palpation over the volar aspect of the metacarpal head results in local tenderness. The examiner can feel a prominence or thickening of the flexor tendon. Pain is aggravated by passive extension or active resisted flexion of the involved digit.

The diagnosis of trigger finger is usually quite obvious from physical examination. No further imaging studies are needed. The goal of treatment of the trigger finger is to restore the normal gliding of the tendon through the pulley system within the synovial sheath. The management of this syndrome is threefold: reduce inflammation, decrease local pressure, and make appropriate worksite changes. First-line treatments include rest from provocative activities and immobilization of the affected digit for 4 to 6 weeks using a splint or buddy taping to an adjacent finger. Splinting is encouraged to reduce pressure and tension on the flexor tendon, maintaining the MCP joint at 10 degrees of flexion while permitting active IP joint motion. Evans et al. reported improvement in 73% of patients with splinting alone (66).

If symptoms persist beyond 6 weeks, local steroid injection into the synovial sheath at the level of the A-1 pulley may decrease inflammation and edema within the pulley and the flexor tendon. There are a few small randomized controlled trials demonstrating the efficacy of steroid injections (67,68). There are not clear guidelines as to when these injections can be repeated, but the majority of patients respond to a single injection. Marks and Gunther demonstrated an 84% cure rate with one injection, which improved to 91% with a second steroid injection (69). Surgery is recommended for refractory cases of trigger finger and is generally a simple outpatient procedure.

### de Quervain's Tenosynovitis

The extensor tendons of the wrist are grouped into six compartments. de Quervain's tenosynovitis occurs when there is inflammation and/or entrapment of the tendons in the first dorsal compartment, namely the extensor pollicis brevis (EPB) and abductor pollicis longus (APL) tendons. The tendons of the EPB and APL run down the radial aspect of the radius coursing over the prominence of the radial styloid before insertion into the thumb. The tendons share a common synovial-lined sheath within an osseofibrous canal.

Disease within the first compartment is precipitated by repetitive wrist motion, especially thumb flexion combined with ulnar deviation of the wrist (70). Typical activities that may precipitate the condition include buffing, wringing, grinding, polishing, sanding, sawing, cutting, and screwdriver use (8). de Quervain's has been described in waitresses, hospital workers, garment workers, machine operators, and domestic cleaners (71,72).

The patient with de Quervain's typically complains of pain and swelling about the region of the radial styloid, especially during grasping movements with the thumb. Swelling and crepitus may be palpated along the radial forearm if significant fluid is present in the tendon sheath. Finkelstein's test involves actively flexing the thumb into the palm while making a closed fist, while having the examiner passively deviate the wrist in an ulnar direction. A positive test is marked by significant discomfort in the region of the radial styloid and maybe more suggestive of EPB than APL dysfunction (73). A positive Finkelstein's test is suggestive of de Quervain's but may be positive in carpometacarpal osteoarthritis of the thumb as well. Another useful clinical test is resisted thumb extension at the MCP with the wrist maintained in radial deviation.

The mainstay of treatment involves curtailing activities that place great shear force on the first dorsal compartment. Acute therapies can involve ice application for 15 minutes every 6 hours or NSAIDs. Orthotic devices such as a thumb spica splint or buddy taping the thumb to the index finger may be needed to further limit motion and rest the APL and EPB tendons. Steroid injection into the tendon sheath of the first dorsal compartment may be a useful adjunct during the acute inflammatory stage to quiet the tenosynovitis. McKenzie reported an improvement in 90% of symptomatic patients treated with one to three injections of hydrocortisone into the tendon sheath at 18-month follow-up (74). Later trials have demonstrated the efficacy of steroid injections with few complications and return to activities in 1 to 3 weeks (75,76). In a small randomized trial, the addition of an oral NSAID did not have an additive benefit to steroid injection therapy for de Quervain's tenosynovitis (77). In chronic cases, steroid injection may be particularly difficult because of stenosis in the tendon sheath. In refractory cases, surgical decompression of the first dorsal compartment may be curative in approximately 90% of cases, with relatively few complications (78).

### Hand-Arm Vibration Syndrome (Vibration White Finger)

HAVS is a constellation of vascular and neuromuscular symptoms associated with high levels of exposure to vibration. This is typically an occupational disorder that results from both increased duration and intensity of exposure to handling vibrating tools or objects, such as jackhammers, drills, or chain saws. Although it is difficult to quantify the threshold intensity or the amount of operating time needed to cause HAVS, a positive correlation of symptoms with cumulative exposure has been shown (79). Onset of HAVS can occur as rapidly as within 3 months of full-time, daily vibration exposure (80). This disorder is most prevalent in forestry workers, construction workers, stone cutters, and shipyard workers (79,81).

The clinical presentation of HAVS includes vascular, sensorineural, and musculoskeletal symptoms. The vascular component consists of Raynaud's phenomenon and may be triggered by a cold environment. There is initial digital blanching (associated with vasoconstriction), followed by cyanotic discoloration that eventually resolves into erythema when

blood vessels dilate allowing reperfusion. During this bright red phase of reactive hyperemia, there may be significant pain in the wrist, hands, or fingers. Not all patients will experience all three phases, as some only have the initial blanching phase. The duration of these symptoms varies greatly from minutes to hours. Neurologically, symptoms include tingling paresthesias or numbness. Patients may also note intermittent aching pain in their hands. Grip strength may be reduced due to weakness of the finger flexors or intrinsic hand muscles. In chronic cases, skin ulceration may develop, usually at the fingertips.

There are various tests for the diagnosis of HAVS. Physical exam should include two-point discrimination and vibration perception testing, which can uncover sensorineural dysfunction (82–84). Duplex ultrasonography checks the patency of arteries of the upper limbs. Cold provocation testing utilizes the fact that patients with Raynaud's secondary to HAVS often have prolonged coolness of digits after cold water immersion. Coughlin et al. demonstrated high sensitivity and specificity for cold provocation thermography, in which thermal measurements of the digits are made before and minutes after cold immersion of hands (85). Nerve conduction studies have found sensory nerve conduction velocity slowing in the digits in 36% and across the wrist in 20% of patients in advanced stages of HAVS (86). HAVS patients often have both median and ulnar neuropathies (87). Another objective measure involves recording finger systolic blood pressures (FSBP) at baseline and again after exposure to cold. The cold temperatures result in greater vasoconstriction, which is measured by the FSBP decrease in symptomatic HAVS patients (88). Poole et al. found a specificity of 90% to 95% and sensitivity of 43.5% to 60% for this technique (89).

Treatment of HAVS begins with limiting exposure to hand vibration, using antivibration gloves and coated tool handles, and ensuring proper technique in handling equipment (90). Avoidance of contact with cold objects or maintaining warm hands in cold environment can decrease bouts of Raynaud's. Smoking cessation is highly recommended because of its vasoconstrictive effects on peripheral arteries (80). Medications such as calcium channel blockers, nitrates, pentoxifylline, and NSAIDs may help reduce symptoms especially if used in combination (91,92).

## NERVE ENTRAPMENT SYNDROMES

### Carpal Tunnel Syndrome

The carpal tunnel is an enclosed space formed by the sheath of the flexor retinaculum and the carpal bones. Within the tunnel lie the median nerve and tendons of the flexor digitorum superficialis, flexor digitorum profundus, and flexor pollicis longus (FPL). When the median nerve becomes entrapped in this space, the resulting numbness, paresthesias, weakness, and atrophy of intrinsic hand muscles are known as carpal tunnel syndrome (CTS).

There are numerous epidemiologic studies associating repetitive movement and/or forceful exertions with CTS. CTS

has also been associated with vibrations and awkward postures, but there is less epidemiologic support for this. Chiang et al. studied fish processing workers and categorized them into three groups based upon levels of repetitiveness and force exerted (37). Prevalence rates of CTS in workers performing tasks with high force and high repetitiveness was 28.6%, those with tasks with either high force or high repetitiveness had a rate of 15.3%, and those with low force and low repetitiveness had a rate of 8.2%. Another study evaluated 56 workers at a single supermarket and found an OR of 8.3 between CTS development in workers with highly repetitive and forceful wrist motions versus those with low exposure (93). In this study, both clinical symptoms and electrodiagnostic criteria established a diagnosis of CTS. Silverstein et al. conducted a broader study of 652 workers across multiple occupations and found an OR of greater than 15 between CTS and highly repetitive and forceful work (defined as force >6 kg) versus low force and repetitiveness (94). Aside from epidemiologic evidence, some studies have analyzed carpal tunnel pressures. Gelberman et al. compared the carpal pressures of 15 CTS patients with 12 controls. This study found normal subjects to have carpal pressures of 2.5 mm Hg at neutral wrist position, which increased to about 30 mm Hg with 90 degrees of wrist flexion or extension. In those with CTS, baseline pressure was 32 mm Hg in neutral position and increased to 94 mm Hg at 90 degrees of wrist extension (95). Another study suggested that compressive forces may lead to persistent impairment of intraneural microcirculation due to mechanical injury to blood vessels (96).

In spite of numerous studies implicating CTS as a CTD, there is some evidence to the contrary. One common flaw to many CTS studies is the failure to control for concurrent underlying medical conditions associated with CTS, including diabetes, obesity, rheumatoid arthritis, or thyroid problems. Atcheson et al. studied 297 patients diagnosed with occupational CTS and found a high prevalence of concurrent medical conditions that may have contributed to their carpal tunnel symptoms (97). Finally, there are some studies that have failed to demonstrate a positive correlation between cumulative trauma and CTS. Schottland et al. measured the median nerve latencies in poultry processing workers and found no significant association between slowing of either motor or sensory latencies and repetitive work (98).

The initial symptoms of CTS are, typically, sensory dysfunction in the form of numbness and paresthesias (often described as tingling “pins and needles”). These symptoms occur in the median nerve distribution, affecting the palmar aspect of the thumb, index finger, middle finger, and radial half of the ring finger. Involvement of the entire hand, however, is not uncommon. Symptoms classically worsen during the night, which may be related to increased edema secondary to a nocturnal increase in tissue pressures. A “flick sign,” in which the patient vigorously shakes the hand in an attempt to relieve symptoms, has been reported in as high as 93% of those with CTS (99). Weakness may follow sensory symptoms after a variable amount of time and may lead to thenar muscle atrophy.

The diagnosis of CTS is based largely upon history and physical examination and can be further supported by electrodiagnostic studies. On exam, the Tinel’s and Phalen’s tests are provocative tests that are suggestive of CTS. In Tinel’s test, the median nerve is percussed at the wrist, and the subject is asked if this results in pain or paresthesias in a median nerve distribution in the hand. For Phalen’s test, a subject maintains wrist flexion for 60 seconds after which typical CTS symptoms are reproduced in a positive test. One study found the positive predictive value (PPV) of the Tinel’s sign alone to be 55% whereas the PPV of a positive Tinel’s plus a classic diagram of hand pain to be 71% (100). Electrodiagnostic testing offers additional objective data of CTS, but one study has demonstrated that median neuropathy is present in 18% of 125 randomly selected individuals who had no symptoms of CTS (101).

Management of CTS begins with appropriate workplace changes including reducing the repetitiveness of tasks and limiting “wrist-intensive” duties. Nonsurgical management often consists of nighttime splinting, NSAIDs, tendon/nerve gliding exercises, and local corticosteroid injections. One randomized trial found nocturnal wrist splinting to be beneficial in symptom reduction at 4 weeks compared to no treatment (102). Goodman and Gilliatt reported that 34 of 51 patients treated with splinting alone were symptom free after 6 to 30 months of follow-up (103). Giannini et al. reported relief of symptoms in 90% of CTS patients within 45 days and in 93% after 6 months, in those who received steroid injection (104). A 2007 systematic review concluded that steroid injections have greater symptom improvement than placebo at 1 month (105). Finally, for patient refractory to these nonsurgical measures, surgical decompression can be employed and offers many patients sustained symptom relief.

### **Pronator Syndrome**

The median nerve exits the upper arm and enters the forearm by passing under the bicipital aponeurosis between the two heads of the pronator teres. Entrapment of this nerve can occur at four points: under the ligament of Struthers in the medial distal arm, under the lacertus fibrosus (a thickened aponeurosis from the biceps tendon to the flexor forearm mass), under the pronator teres, or under a thickened or fibrous portion of the flexor digitorum superficialis. These four entrapment areas can be differentiated based on history and physical examination. The pronator syndrome may occur in those who perform jobs requiring repeated pronation, supination, lifting, or handling of heavy objects (106).

Clinically, the patient with pronator syndrome often presents with forearm pain, numbness, and weakness. In distinction from CTS, weakness in proximal median innervated muscles such as the flexor carpi radialis or pronator teres may be present. In addition, the distribution of sensory abnormality will include the thenar eminence in pronator syndrome. This area is spared in CTS (107). Entrapment at the ligament of Struthers and at the lacertus fibrosis can be accentuated by resisted full elbow flexion or resisted supination. Entrapment

at the pronator teres and flexor digitorum superficialis can be accentuated by resisted forearm pronation and resisted middle finger flexion, respectively (108).

Treatment should begin with duty modification and relative rest. NSAIDs can be used to decrease pain. Simultaneously, one should begin physiotherapy to stretch and strengthen the involved area. If conservative methods fail, surgical resection of fascial bands, tendinous arches, or the ligament of Struthers may be considered. These authors recommend electrophysiologic evaluation prior to surgery to confirm the precise location of the nerve entrapment. In addition, peripheral nerve visualization with MR imaging or musculoskeletal ultrasound (in the hands of an experienced radiologist) can be very useful to exclude space-occupying lesions as an etiology of the compressive neuropathy (109).

### Ulnar Nerve Entrapment

The ulnar nerve arises from the medial cord of the brachial plexus and travels along the medial aspect of the arm and then behind the medial epicondyle in the ulnar groove. It enters the forearm between the two heads of the flexor carpi ulnaris (FCU) and travels in the cubital tunnel. The cubital tunnel is formed just distal to the ulnar groove as the ulnar nerve passes underneath the FCU. This median nerve is covered by the arcuate ligament of Osborne that bridges across the two heads of the FCU. The ulnar nerve then gives off the dorsal and palmar cutaneous branches before passing through Guyon's canal, which is defined by the pisiform and hamate bones and the overlying transverse carpal ligament.

Entrapment or compression of the ulnar nerve within the cubital tunnel is the second most common compression neuropathy in the upper limb after CTS (110). Elbow flexion causes the arcuate ligament to become taut, the FCU to tighten, and the ulnar collateral ligament of the elbow to buckle and encroach into the tunnel (111,112). Apfelberg and Larson demonstrated a 55% narrowing of cubital tunnel volume during elbow flexion (113). The combined movements of shoulder abduction, elbow flexion, and wrist extension result in the greatest increase in cubital tunnel pressure. Repetitive flexion and extension of the elbow itself may chronically irritate the nerve or result in hypertrophy of the arcuate ligament, leading to further compression (114). Cubital tunnel syndrome is commonly seen in occupations involving repetitive elbow flexion, prolonged flexed elbow posture, and repeated trauma or pressure to this area (115). Specifically, these repetitive stresses occur in shoveling, hammering, lifting, and digging (115). Cubital tunnel syndrome has also been noted in assembly line workers because of repetitive elbow flexion and extension (116). Problems arising from leaning on the elbows for prolonged periods have been identified in computer operators at workstations, as well as in truck and taxicab drivers. There has also been an association between cubital tunnel syndrome and sewing machine operators, who also frequently rest their elbows on their workstations (117).

The second most common site for ulnar nerve compression is in the region of Guyon's canal. Chronic focal compression,

ganglion cysts within the canal, ulnar artery thrombosis, or acute blunt trauma to the region may lead to a distal ulnar neuropathy (118). Ulnar nerve entrapment at Guyon's canal was first identified in gold polishers in 1896 and has been subsequently reported in boot makers, secretaries/typists, machine operators, meat packers, pipe cutters, mechanics, and long-distance cyclists (119,120).

Cubital tunnel syndrome initially presents with numbness, tingling, or paresthesias of the fourth and fifth digits and can progress to weakness of grip strength, wasting of ulnar-innervated hand intrinsics, and, finally, a "clawing" of the hand. The symptoms may be worse at night due to flexion of the elbow during sleep (115). There are several provocative examination maneuvers that aid with diagnosis. The elbow flexion test, in which one maintains the elbow in full flexion for one minute, can provoke paresthesias in an ulnar distribution (121). A positive Tinel's sign, in which tapping of the ulnar groove reproduces paresthesias or pain in the fourth or fifth fingers, is suggestive as well. Novak et al. found that the sensitivity of the flexion test at 60 seconds was 0.75 and the specificity 0.99, while the sensitivity of the Tinel's test was 0.70 and specificity 0.98 (122). There are additional tests that assess muscle weakness that occurs in more severe cases of entrapment. Froment's test involves asking the subject to make a fist and grasp a piece of paper firmly between the thumb with an extended IP joint and the index finger. This test assesses for adductor pollicis weakness, which may be present in ulnar neuropathy. Subjects will compensate by firing the median-innervated FPL to grasp the paper between thumb and index finger, but this will result in flexion of the thumb IP joint (Froment's sign). Wartenberg's sign occurs when a subject has difficulty adducting 5th digit when it is extended.

Compression of the ulnar nerve at Guyon's canal may cause variable clinical findings, depending on where the nerve is injured within the canal. Loss of sensory function, motor function, or a combination thereof may be noted. If compression occurs in the proximal aspect of Guyon's canal, the patient will have paresthesias or numbness along the lateral hand and possibly motor weakness of the hand intrinsics. If the lesion occurs at the lower wrist, there can be sparing of the sensory branch to the dorsal aspect of the hand. Finally, if the lesion is at the distal aspect of Guyon's canal, there is usually only sensory loss along the distribution of the superficial branch of the ulnar nerve. Focal pressure applied between the pisiform and the hook of the hamate may induce symptoms.

To confirm the diagnosis of ulnar neuropathy, electrodiagnosis should be employed. Nerve conduction studies and EMG can precisely localize the area of entrapment and suggest an early diagnosis when symptoms are subtle (123,124). Furthermore, it can clarify the nature of pathology by distinguishing axonal degeneration, segmental demyelination, and abnormal nerve irritability from one another (125).

In the industrial setting, the first step in management is to reduce extrinsic compression of the ulnar nerve via relative rest, activity modification, and/or padding. Additional measures include anti-inflammatory medication and nocturnal

splints, which prevent elbow flexion beyond 60 degrees. Seror demonstrated 100% subjective improvement in 22 cubital tunnel syndrome patients who wore a night splint for 6 months. Nerve conduction velocity across the elbow measured at a mean follow-up of 11.3 months was improved by 6.5 m/s for motor nerve conduction and 9.5 m/s for sensory nerve conduction in 16 of 17 patients (126). Elbow padding may help to reduce compression in this area (127). A physiotherapy program beginning with elbow ranging and stretching and then progressing to strengthening of the muscles involved in elbow flexion, extension, pronation, and supination is suggested by the authors. Steroid injections may be a reasonable option, but there are few studies to support this. Hong et al. found that steroid injection did not provide additional benefit to splinting in a small trial of ten patients (128). Finally, surgery is reserved for refractory cases and available options include simple release, nerve transposition, or medial epicondylectomy.

### Thoracic Outlet Syndrome

Thoracic outlet syndrome (TOS) comprises several subsets of conditions that all lead to compression of the lower trunk of the brachial plexus or subclavian vessels along the costoclavicular passages. Categories of TOS include scalenus anticus, costoclavicular, and the hyperabduction syndromes. In the neck, the subclavian artery travels along with the lower trunk of the brachial plexus between the anterior and middle scalene muscles. The subclavian vein typically passes anteriorly to the anterior scalene muscle, but in some cases may also travel along with the subclavian artery between the anterior and middle scalene muscles. The neurovascular bundle then travels between the clavicle and the first rib and underneath the pectoralis minor muscle as it reaches the arm. Compression is theorized to occur at any of these anatomic sites.

Physiologic narrowing of the costoclavicular space can occur with sustained activities requiring hyperabduction of the arms, drooping of the shoulders, and contractions of the scalene muscles. This narrowing can occur in the context of weight lifting, frequent overhead work, or overhead lifting. Additionally, patients with an accessory cervical rib are particularly vulnerable to brachial plexopathy of the lower trunk. Tubbs et al. demonstrated histologic changes in nerves distal to the site of compression by cervical ribs (129).

Clinically, TOS can have vascular or neurogenic symptoms. The classic symptoms consist of paresthesias in the fourth and fifth digits with possible medial forearm involvement. Vascular changes including Raynaud's phenomenon may be present. Hand weakness is seen in true "neurogenic" thoracic outlet compression. Often, the patient may have only a sense of upper extremity fatigue with sustained overhead postures. On physical examination, sensory abnormalities may be apparent in the distribution of the C8/T1 dermatome or lower trunk of the brachial plexus. Provocative maneuvers, such as Adson's, Roo's, costoclavicular, or Wright's hyperabduction test, have low sensitivity and specificity. One study suggested a mean sensitivity of 72% and specificity of 53% of these tests (130). This same study also found the Adson's maneuver to have a PPV of 85%

and the hyperabduction test to have a PPV of 92%. However, another more recent study found these maneuvers to have a high false-positive rate in normal subjects and an even higher false-positive rate in CTS patients (131). More sensitive diagnostic testing includes Doppler studies, MRA, angiography, or nerve conduction studies. One small series of 13 TOS patients (as confirmed by angiography) suggested that Doppler studies are an effective noninvasive diagnostic tool and correctly made the diagnosis in 10 of these 13 patients (132).

Initial management consists of a coordinated program to ameliorate occupationally induced factors, along with physical therapy to stretch implicated muscles (scalenes, pectoralis minor, trapezius, and levator scapulae). In addition, strengthening of scapular elevators and stabilizers, such as the upper/middle trapezius and rhomboid muscles, is used to improve posture and increase the area within the costoclavicular space (133). Postural biomechanics must be emphasized, as this likely underlies most cases of mild to moderate TOS. A study from Kuopio University Hospital, which stressed normalization of the motion of the cervical spine and upper thoracic aperture via conservative therapies, demonstrated 88% patient satisfaction. In this study, satisfaction was predicted by normalized grip strength, negative Tinel's sign, and return to work (134).

Surgery for resection of anomalous fibrous bands, thickened musculature, accessory cervical rib, or first rib is reserved for refractory cases thought to be caused by those anatomic factors. Studies suggest that transaxillary first rib resection may provide better results than supraclavicular neuroplasty without rib resection (135). The outcome of TOS surgery among injured workers may be worse than the general population. The strongest predictors for remaining disabled were significant work disability prior to surgery, longer time between injury and TOS diagnosis, and older age at injury (136). Botox chemodenervation of the scalene muscles may be helpful in alleviating symptoms in TOS patients awaiting definitive surgical decompression (137).

### Low Back Pain

LBP is one of the most common CTDs and is encountered in myriad occupations ranging from sedentary jobs, such as truck driving or secretarial work, to those requiring frequent lifting, such as nursing or construction. A prospective, longitudinal study in South Manchester revealed that lifting objects weighing more than 25 lb, pushing/pulling heavy objects, and standing or walking for prolonged periods were associated with a higher incidence of LBP, especially among female workers (138). Vibration to the spine has been tied to LBP in forklift drivers and crane operators (139,140). Psychosocial factors play a significant role in many cases of LBP. One multivariate analysis reported an OR of 2.52 for LBP incidence in those with psychological distress (141). In an initially asymptomatic VA cohort, depression was the single greatest baseline predictor of incident LBP (hazard ratio = 2.3) (142). A thorough discussion of the pathophysiology, diagnosis, and management of LBP is beyond the scope of this chapter and can be found in Chapters 33 and 68.

## Ergonomic Interventions

Ergonomic workplace modifications are increasingly utilized to prevent CTD. The Occupational Safety and Health Administration, a division of the U.S. Department of Labor, has published workplace guidelines for different industries including health care, retail groceries stores, shipyards, etc. The Center for Disease Control also has a concise summary of ergonomic considerations in a variety of workplace settings available at <http://www.cdc.gov/od/ohs/ergonomics/ergohome>. While an in-depth discussion of ergonomic evaluation and design is beyond the scope of this chapter, some general considerations are introduced below.

### Positions/Postures

- The worker should avoid extreme flexion of the elbow, extreme flexion or extension of the wrist, and sustained supination or pronation of the forearm.
- During repetitive work (e.g., typing), the upper extremity should be relaxed at the sides, with the elbows flexed no more than 70 to 90 degrees.
- Avoid prolonged maintenance of the elbow in the overhead position during repetitive or sustained activities.
- Avoid activities with sustained grip or pinch.
- Avoid repetitive radial or ulnar deviations of the wrist.
- Avoid sitting in the same position for extended periods of time. Take breaks to stretch and walk around.

### Seated Computer Workstation

- The height of the workstation is a very important component in the overall design, as small changes in height alone may influence the positioning of the neck, shoulders, elbows, and wrists. If a desk area is too high, the worker is forced either to abduct or elevate the shoulders, forcing increased sustained muscle contraction along with compensatory ulnar deviation at the wrists. If the desk area is too low, the worker may be forced to slouch in the chair, with rounding of the upper back, flattening of the lumbar lordosis, and an increase in forward head posture.
- Telephone headsets could be used if extensive or frequent telephone calls are expected.
- The top of the computer monitor should be in line with the worker's eyes, allowing for a natural downward gaze angle of 15 degrees toward the middle of the screen. This position also allows the worker to maintain the normal lordotic curve of the cervical spine, avoiding the forward head position.
- The optimum distance from the monitor is 12 to 18 in. If the monitor is too close, the worker will experience eye strain; whereas if it is too far away, the worker is forced to slouch forward, increasing stress throughout the entire spine. Also avoid variation in the distance of eyes to the monitor to avoid frequent changes in focus.
- While seated, the worker's feet should rest on the floor with the knee flexion maintained between 90 and 105 degrees. If

the feet are not resting on the ground, a footrest should be used.

- The ideal seat depth should allow 1 to 4 in. between the popliteal fossa and the front edge of the seat. A shorter depth seat will require the buttocks and upper thighs to sustain excessive pressures, whereas a longer seat depth may impede circulation behind the knees.
- The back rest should support the lumbar curve while maintaining the thoracic spine in contact with the chair back. It may be necessary to add a rolled towel or lumbar support if the back rest does not sufficiently support the natural lordosis of the lumbar spine.
- Adjust keyboard and mouse height so that elbows can be flexed at a 90-degree angle and forearms are parallel to the ground.

Many workplace environments have already implemented ergonomic design changes. Further research and studies are needed in this area to determine optimal positioning and ways to avoid repetitive strain.

## CONCLUSION

CTDs are common in our society and account for a large fraction of all occupational injuries. Clinicians managing patients with CTDs should not only have knowledge of the pathophysiology and biomechanics at the core of the problem but should be familiar with common workplace and recreational scenarios that would lead to these disorders. This allows the examiner to perform a focused history and physical exam. Next, an appropriate diagnostic workup consisting of imaging, electrophysiologic studies, and labs can be selectively ordered. The clinician should then take the lead in coordinating the different aspects of treatment. The mainstay of treatment should focus on correction of underlying causative factors. This involves activity restriction, if possible, and modifying equipment and posturing techniques in accordance with ergonomic principles. Further conservative treatment involves a regimen of targeted strengthening or stretching exercises, use of orthotic devices, modalities, and anti-inflammatory medications. Appropriate management of pain should be a priority at all stages of treatment. While the majority of CTDs respond to conservative therapy, surgical consultation should be sought in refractory cases.

Although our knowledge of the prevention and management of CTDs has been enhanced by numerous research studies, further controlled studies are needed in this area. Future areas of clinical research include evidence-based ergonomic interventions for primary prevention, specific physiotherapy regimens, the role of newer therapeutic modalities (i.e., acupuncture), and long-term outcomes research for nonsurgical and surgical interventions. Additionally, basic science research of these disorders will lead to a better understanding of their pathophysiology, which may lead to new therapeutic targets. Overall, the management of CTDs continues to be an important and challenging field.

# Hand Disorders

Our hands are our primary tools for interacting with our environment. One may argue that the most significant function of the shoulder, elbow, and wrist is to position the hand in space. Once the hand is positioned, it is able to proceed with its functional task. Therefore, any abnormalities of hand function are important to evaluate and when possible treat, because of the critical role that our hands play in our daily routines.

The anatomy of the human hand is extremely complex, with many intricate mechanisms that allow us to grip a tennis racket, hold a pencil, or play the piano. Perhaps because of its intricacy, the care of the hand, both surgical and nonsurgical, has been relegated to specialists in hand surgery. Physiatrists have stayed on the sidelines. However, with a thorough understanding of the hand anatomy and pathophysiology, a well-trained physiatrist is in a strong position to manage all medical aspects of hand care.

The goal of this chapter is to provide a brief overview of common hand problems, their pathophysiology, and their treatment. Most of the treatment discussed is nonsurgical in nature. However, a brief overview of surgical options and their indications is also provided. A more detailed account of these clinical entities and their treatment is available in hand surgical texts and in this chapter's reference section.

## CARPAL TUNNEL SYNDROME

Carpal tunnel syndrome (CTS) is the most common compressive neuropathy in the upper extremity (1) (Tables 37-1 and 37-2). This condition typically causes paresthesias in the median nerve distribution. Fifteen percent of the general population has symptoms consistent with CTS. The prevalence of electromyogram-confirmed CTS is 3% in women and 2% in men. Prevalence is greatest in women older than 55 years (2). It is more frequently found in people who are obese or smoke and in those with diabetes mellitus (3,4). Cervical root compression and thoracic outlet abnormalities can also be associated with CTS (5). No hand preference, dominant or nondominant, has been identified, and 60% of patients have bilateral symptoms (2,6). Many factors contribute to the development of CTS, including vibration, local pressure over the carpal tunnel, awkward wrist positions, and forceful hand positions (7-9). However, there remains considerable debate about whether CTS is a result of repetitive stress without other factors being present (10,11). Food processing, construction, and manufacturing are occupations that have a higher incidence of CTS (12). Debate

remains as to the association of CTS and computer keyboard work (13-15). It has even been hypothesized that keyboard work may be associated with less CTS (16).

The diagnosis of CTS is usually straightforward and is based on history and clinical evaluation. Electromyogram (EMG) is often used for diagnostic confirmation of CTS. It can measure the extent of damage and demyelination of the median nerve (15). In mild cases, there may be an absence of electromyographic and nerve conduction changes. As symptoms progress, sensory distal latency is usually the first abnormal EMG finding. Therefore, the diagnosis of CTS is first established on history and clinical findings and then may be confirmed by EMG evaluation. Recently, there have been multiple reports on using ultrasound evaluation of the median nerve to diagnose CTS. These studies have shown that there is a change in the cross-sectional area of the median nerve when CTS is present (17-19).

The carpal tunnel is located just distal to the palmar wrist crease. It is surrounded on three sides by the carpal bones, creating an arch. The radial wall is bordered by the scaphoid and trapezium, the dorsal is bordered by the lunate and capitate, and the ulnar wall is composed of the hamate. The arch is covered by a thick fibrocartilaginous band called the *flexor retinaculum* (or transverse carpal ligament.) Nine tendons—two tendons that flex each finger, flexor digitorum superficialis (FDS) and flexor digitorum profundus (FDP), and one to the thumb, flexor pollicis longus (FPL)—course through the carpal tunnel (20). The median nerve traverses with these tendons through the tunnel on its way to provide innervation to the thenar muscles and to provide sensation to the radial three and one half digits (Fig. 37-1).

CTS is thought to be the result of increased pressure within the fibroosseous tunnel. Normal pressure within the carpal tunnel is 7 to 8 mm Hg with the wrist in neutral. Increased pressure of 30 mm Hg can result in symptoms of CTS and 90 mm Hg can be observed with wrist flexion and extension (21,22). This pressure increase causes relative ischemia and impaired nerve conduction of the median nerve (23,24). If abnormally increased pressure continues, segmental demyelination occurs. The median nerve sensory fibers are the first to be affected owing to their extensive myelination and high metabolic demands. Prolonged pressure causes injury to the motor fibers, and weakness ensues. The prevalence of CTS increases with pregnancy, inflammatory arthritis, distal wrist fracture, amyloidosis, hypothyroidism, diabetes, acromegaly, and in individuals who use corticosteroids and estrogens (13,20,25). One third of all cases of carpal tunnel are associated with these

**TABLE 37.1** Carpal Tunnel Syndrome

Physical Exam	Electromyogram	Causes
Tinel's at wrist	Prolonged distal latency of median sensory, possible motor	Space-occupying lesions (trauma, tumor, inflammation)
Grip test	Needle exam findings in thenar muscles only	Direct trauma
Carpal tunnel compression, positive Phalen's		Physiologic compression
Two-point discrimination, >6 mm		Possibly vibration
Opposition strength		

medical conditions (26); diabetes is the most common association (13,26).

The typical symptoms of CTS are numbness, tingling, pain, burning, or a combination of these (27). These symptoms occur in the radial three and one half digits: the thumb, index, middle, and half of the ring finger. CTS often causes nocturnal awakening secondary to the hand paresthesias. These nocturnal symptoms are 51% to 77% sensitive and 27% to 68% specific for CTS (28). Gripping, driving, holding vibrating objects, or prolonged pinching, such as holding a book, may result in increased paresthesias. Many patients describe relief of their symptoms with shaking of the hands (29). With progression, patients may describe an awkward feeling or weakness of the hand and begin dropping objects.

Physical examination (Table 37-3) usually begins with the exclusion of any cervical, shoulder, or elbow pathology, which

**FIGURE 37-1.** Carpal tunnel syndrome. Median nerve traversing with the flexor tendons through the carpal tunnel providing sensory innervation to the radial three and one half fingers and motor innervation to the thenar muscles.

may produce similar symptoms. C6 radiculopathies are often confused with CTS because the sensory symptoms involve the radial aspect of the hand. Strength testing should include wrist flexion-extension, grip, and thumb opposition. Specific CTS provocative tests include Phalen's test, in which the wrist is held in full passive wrist flexion. This position increases pressure within the carpal tunnel and may reproduce paresthesias

**TABLE 37.2** Diagnosis and Treatment of Hand Disorders

Diagnosis	Symptoms and Signs	Prescriptions
Trigger finger	Locking of digits in flexion, snapping, popping, tender nodules, crepitus	Rest, activity modification, modalities, cortisone injection, A-1 pulley release
de Quervain's	Radial wrist pain, positive Finkelstein's	Splint, modalities, cortisone injection, first dorsal compartment release
Dupuytren's	Superficial palmar nodules, painless flexion contractures	Possibly collagenase injection, surgical release
Carpal tunnel syndrome	Nighttime hand paresthesias, positive Tinel's, carpal tunnel compression, Phalen's	Splint, activity modification, cortisone injection, surgical release
Cubital tunnel syndrome	Ulnar hand pain and paresthesias, positive Tinel's at elbow, possible interosseous weakness	Elbow protection, surgical release, nerve transposition
Basilar thumb degenerative joint disease	Pain at base of thumb, positive grind maneuver	Splint, activity modification, NSAIDs, cortisone injection, surgical reconstruction

TABLE 37.3	Evaluation: History and Physical Findings
Duration/severity	
Presence of numbness: location along thumb, index, middle and half of ring finger, constancy. Use of Semmes-Weinstein monofilaments to determine sensory loss	
Nocturnal paresthesias	
Weakness of grip and/or pinch	
Muscle wasting of the thenar muscles in absence of subluxation of the first MCP joint	
Provocative testing: Tinel's sign: paresthesias upon tapping the median nerve; Phalen's sign: the reproduction of symptoms in the median nerve distribution (e.g., thumb, index, middle and half of ring finger), after 1 min of forceful flexion of the wrist while the thumb is flexed into the palm	

in individuals with CTS. This test has a wide reported range of sensitivity and specificity (40% to 80%) (28,30,31). The time to the development of paresthesias should be noted because it can be used to monitor change with treatment. Tinel's test involves tapping the median nerve just proximal to the transverse carpal ligament (32). Reproduction of the paresthesias into the hand by the Tinel's test is 20% to 60% sensitive and 67% to 87% specific for CTS (30,31). Carpal tunnel compression involves pressure placed with the examiner's thumb or index and long fingers over the carpal tunnel. This pressure is maintained for 30 seconds to 1 minute and if positive will reproduce paresthesias. Durkan (33) believes that this test is more sensitive and specific for CTS than Tinel's or Phalen's test.

Treatment of CTS begins with modification of repetitive or awkward activities that precipitate paresthesias. Splinting the wrist in a neutral position at night has been demonstrated to reduce symptoms in 80% of patients (34,35). Nonsteroidal anti-inflammatory drugs (NSAIDs), diuretics, vitamin B<sub>6</sub>, and oral steroids have been tested, but no specific recommendations have been given for their prolonged usage (27,36). Therapeutic interventions such as ultrasound, iontophoresis, gentle stretching and strengthening exercises, ice, and carpal tunnel protection principles may be employed. Their application is clinically accepted but not scientifically determined to be efficacious.

Protection principles stress avoidance of positions or activities that increase pressure within the carpal tunnel. Nerve and tendon gliding exercises have been described and are thought to be useful (37–39). Acupuncture and yoga have also been demonstrated to decrease symptoms (40).

Corticosteroid injections into the carpal tunnel are recommended if splinting and other conservative measures fail to reduce the symptoms. They have been shown to decrease symptoms in 75% of patients and improve nerve conduction (41–44). These injections are performed in a sterile fashion with needle placement ulnar to the palmaris longus. The needle is directed dorsally, distally, and radially at a 45-degree angle. In patients with severe CTS, 80% have return of symptoms in 1 year despite appropriate conservative care (21). If the patient has signs or symptoms of constant numbness, loss of sensation, or thenar muscle atrophy lasting longer than 1 year, serious consideration of surgery is recommended (20). There are many approaches to a CTS release. Traditionally, an open incision has been performed and the transverse carpal ligament resected. Endoscopic CTS release can be performed but may pose a slightly greater risk for injury to the median nerve (45). Relief of symptoms is similar in the two approaches, but patients typically return to work quicker with the endoscopic technique (46,47). Postoperative rehabilitation versus home exercises seem to have the same outcomes, except that it has been shown that rehabilitation hastens the time to return to work (48).

ULNAR NEUROPATHY

The ulnar nerve may be compressed at a number of points along its course. There are four areas of common compression around the elbow and one area at the wrist at Guyon's canal. The areas of compression about the elbow include the medial intermuscular septum, the arcade of Struthers, the cubital tunnel, and the deep flexor aponeurosis (49) (Fig. 37-2). Compression of the ulnar nerve at Guyon's canal may be secondary to thrombus at the ulnar artery (hypothenar hammer syndrome) or to ganglion cyst from the pisotriquetral joint or the triquetral hamate joint.

Ulnar neuropathy at the elbow produces weakness of the wrist ulnar deviators, the lumbricals of the ring and small fingers,

FIGURE 37-2. Ulnar neuropathy: points of compression in the elbow region.

**FIGURE 37-3.** Benediction sign.

and all of the interosseus muscles. Sensory loss is at the ulnar side of the hand extending from the wrist crease to the tips of the small finger and ulnar half of the ring finger both dorsally and in a palmar direction. Entrapment at Guyon's canal spares the wrist muscles as well as the dorsal hand cutaneous sensation. A small sensory branch of the ulnar nerve, the superficial cutaneous branch, is also spared, thus preserving a small area of sensory innervation to the base of the hypothenar eminence. Patients may complain of pain at the medial elbow and anywhere along the course of the ulnar nerve. Numbness and paresthesias may also be present. Weakness is usually a later sign. Patients may develop atrophy of the interosseus and hypothenar muscles and show posturing of their hand. Because the extrinsic finger extensors are spared, a mismatch of strength is seen between the extrinsic and intrinsic finger muscles. This disparity produces the classic "claw" deformity of the fingers. Because the lumbricals of the index and long fingers are median nerve innervated, these two digits may show normal posturing. This "clawing" of the ring and small fingers is called the "benediction sign" (Fig. 37-3).

The conservative treatment of ulnar neuropathy at the elbow is based largely on protection principles. The ulnar nerve in the cubital tunnel lies in a position that is vulnerable to trauma. Therefore, counseling the patient to avoid leaning the elbow on tables, counters, or arm rests may prevent repetitive trauma to the nerve. The patient may also wear various forms of elbow pads or protective elbow sleeves. These not only cushion the cubital tunnel area but also serve as a constant reminder to the patient to avoid pressure on the elbow.

Even though the cubital tunnel resides at the center of rotation for the elbow joint, flexing the elbow may still stretch the ulnar nerve. This is possible because the ulnar nerve may show as much as 21.9 mm of excursion at the elbow and 23.2 mm at the wrist with combined motion of the shoulder, elbow, wrist, and fingers (50). This excursion may be inhibited by fibrosis or entrapment of the nerve at one or more of the aforementioned compression sites. Thus, the normal gliding of the ulnar nerve may be limited and cause tension on the nerve with movement either proximal or distal to the elbow as well as with elbow flexion and extension. The patient should be counseled to avoid prolonged elbow flexion or posturing of the upper extremity in any position that reproduces their symptoms.

Surgical decompression or transposition of the ulnar nerve should be considered when the site of compression is clear either by EMG findings or by imaging and when the symptoms are progressive or debilitating. Many types of idiopathic ulnar neuropathies may be unresponsive to surgical treatment or may improve spontaneously. Nonetheless, when invasive treatment is considered, there are three major categories of surgical treatments for ulnar neuropathy at the elbow (51). The first is simple decompression of the nerve usually combined with medial epicondylectomy. The second and third are subcutaneous and submuscular transpositions of the ulnar nerve. In general, greater amounts of dissection around the elbow lead to greater chances of postoperative elbow stiffness. Moreover, the amount of manipulation of the ulnar nerve is directly related to the chances of damage or continued neuropathy postoperatively. Therefore, the simpler procedures of decompression tend to be the safest. However, placing the ulnar nerve anterior to the medial epicondyle protects it from direct trauma and from stretching. In addition, the deeper the nerve is buried, the less chance for further trauma to the nerve.

## THUMB CARPOMETACARPAL OSTEOARTHRITIS

Basilar thumb osteoarthritis is the most common symptomatic arthropathy of the hand. Thirty-three percent of postmenopausal women older than 50 years have radiographic evidence of osteoarthritis of the thumb carpometacarpal (CMC) joint (52). The etiology of CMC arthritis is likely to be multifactorial, including genetic, environmental, and physiological contributions (53). The thumb CMC joint is a double-saddle configuration. This configuration allows for movement in multiple planes such as flexion-extension, adduction-abduction, and pronation-supination. Sixteen ligaments have been described stabilizing the trapezium and the CMC joint (54). The most important of these is thought to be the so-called beak ligament or deep anterior oblique ligament. Ligamentous laxity plus axial loading of the joint are thought to be major contributors to the development of osteoarthritis at the base of the thumb. However, there may also be a link between hand osteoarthritis and obesity (55).

Classification of the thumb OA is radiographic and is graded according to the change in the trapeziometacarpal space, degree of synovitis, and subluxation. Stage 1 is associated with a normal joint space, whereas stages 2 to 4 have a decreased joint space. Stage 3 has obligatory osteophyte changes and sclerosis of the joint. Stage 4 has all of the observations plus involvement of the scaphotrapezial joint (56). Symptoms vary with each stage.

In the treatment of basilar thumb degenerative joint disease (DJD), one tries to manage the symptoms. No cure is known. We are not even sure that we can slow the progression of the disease. Ideally, the patient acquires new prehensile patterns and adaptive equipment in order to minimize symptoms and maximize function. No single intervention is necessarily superior to others. There is no specific time frame or window of opportunity to follow. The CMC joint biomechanics is such that any pinch force generated at the thumb and

index finger is greatly magnified at the CMC joint interface. In fact, 1 kg of pinch force translates to 12 kg of intra-articular pressure; thus, one strives to minimize fingertip-to-fingertip pinch activities (57). When pinching cannot be avoided, one tries to increase the size of the objects being pinched. In other words, the greater the distance between the thumb and the fingertip, the less pressure on the CMC joint; therefore, enlarging the grip of tools or objects that are being gripped decreases the pressure at the base of the thumb.

Twisting activities also stress the CMC joint by causing a torque or twisting force on the joint. Therefore, various gadgets such as key holders and electric can openers may be helpful. In addition, one may use pens, kitchen utensils, or gardening implements with built-up grips. Many companies manufacture such items.

Splints are used to help stabilize the thumb, reducing pain and enabling more symptom-free function. There are two commonly used splints for this problem: a short opponens splint which is hand-based and crosses the first metacarpophalangeal (MCP) joint; and a long opponens splint which is forearm-based, supports the wrist, and crosses the interphalangeal joint. Patients typically best tolerate the long opponens, forearm-based splint at night and prefer the less obstructive hand-based splint for daytime activities. These splints usually put the thumb in palmar abduction with the MCP in 30 degrees of flexion. Several authors have documented benefits from splinting in stabilizing the joint and providing pain relief (53,58). Others have found studies of the efficacy of splints to be methodologically weak and unconvincing (58a). Splints usually are not successful in symptom reduction when there is fixed deformity of the joint. A review of the evidence for splinting the CMC joint in arthritis is available (59).

Many patients use pain-relieving modalities such as contrast baths, hot-water soaks, or paraffin baths. Anti-inflammatory medications are often used for pain control. In addition, one may consider cortisone injections into the CMC joint (60). If the patient has involvement of the scapho-trapezio-trapezoidal (STT) joint, this may be injected at the same time with a single needle stick.

As a last resort, some patients may consider surgical options for basilar thumb DJD. The most common procedure used to treat this problem is ligamentous reconstruction of the joint (61). The trapezium is wholly or partially excised. The base of the first metacarpal is then reattached to the carpus using a tendon slip from the flexor carpi radialis (FCR), the abductor pollicis longus (APL), or the extensor pollicis brevis (EPB). Various techniques are used to weave the tendon between the bases of the first and second metacarpals with the distal scaphoid. Some variations also employ the remaining tendon slip as a cushion to fill in the gap left by the trapezium. This is also called the ligamentous reconstruction tendon interposition (LRTI) or the “anchovy” procedure. Although the tendon reconstruction procedures help restore mobility of the thumb and reduce pain, they are not suited for heavy activities or manual labor. The patients requiring a large amount of grip strength and durability would be better served by arthrodesis of the joint (62,63). This allows for quicker recovery

and preservation of grip strength. The tendon reconstruction method requires 6 months of recovery and often only results in 60% to 70% of normal grip and pinch strength (64). Various interposition arthroplasty procedures are less common and are not as well established as tendon or fusion procedures.

Other sequelae of osteoarthritis, such as instability or pain of the first MCP joint, may contribute to pain and prehensile abnormalities.

## de QUERVAIN'S TENOSYNOVITIS

de Quervain's tenosynovitis is characterized by pain on the radial aspect of the wrist at the first dorsal compartment. This insidious condition most commonly affects women between the ages of 35 and 55 years (65,66). Women are affected 10 times more frequently than men. There does not appear to be a predilection for dominant or nondominant hand nor for race. Repetitive, prolonged unaccustomed posturing of the thumb or nonneutral wrist movements usually provoke symptoms (67). Waitresses, nurses, garment workers, maids, assembly line workers, and machine operators are at greater risk for development of this condition (68–70).

The extensor tendons to the fingers and wrist travel through six dorsal compartments of the wrist. The first (most radial) dorsal compartment contains the EPB and the adductor pollicis longus (Fig. 37-4). These tendons course through

**FIGURE 37-4.** de Quervain's tenosynovitis. The first dorsal compartment contains the EPB and adductor pollicis longus tendons.

an osteofibrous canal to their insertion on the metacarpal and proximal phalanx of the thumb. A significant angulation is present as these tendons traverse over the radial styloid, placing the tendons at risk for repetitive injury (71). The function of these muscles is to position the thumb in extension and abduction in preparation for gripping and pinching.

de Quervain's tenosynovitis is initially the result of inflammation within the first dorsal compartment. Frequent reoccurrence of this condition results in a reactionary degenerative thickening of the extensor retinaculum and synovial tendon sheath (72,73). In these chronic states, inflammation is absent (74,75). The thickening results in a mechanical stenosis within the first dorsal compartment, causing impingement of the two tendons (76).

The primary symptoms are pain and swelling over the radial styloid process with progression up into the radial aspect of the forearm or distally into the thumb (73). Pain increases with grasping, adduction of the thumb, or ulnar deviation of the wrist. The symptom complex is usually gradual in onset, but traumatic etiologies have been described (72,73).

On physical examination, patients usually have tenderness with palpation over the fibroosseous first dorsal compartment. Pain is commonly elicited with resisted thumb extension and abduction. A positive Finkelstein's test is pathognomonic for de Quervain's tenosynovitis (73,77). This test is performed by flexing the thumb into the palm and making a fist around the thumb. The wrist is then *passively* deviated ulnarly. Increased pain in the region of the radial styloid with this maneuver is considered positive.

de Quervain's tenosynovitis is a clinical diagnosis. X-rays have not been found to be beneficial. Other conditions with a similar presentation include peripheral neuritis, collagen-vascular diseases, sprains of the CMC joint, arthritis of the CMC joint, fracture of the distal radius, ganglions of the wrist, acute calcific tendinitis, and aberrant CTS (78,79).

Activity modification is often the most important consideration in conservative treatment. Elimination of highly repetitive activities that include pinching or gripping is beneficial (66). Immobilization of the thumb in a forearm-based thumb spica splint offers protection and rest. Heat modalities, stretching of the first dorsal compartment muscles, and ice may offer relief of symptoms. To date, there has not been an outcome study on the use of modalities and exercise for this condition.

Injection of local steroids has been shown to be of benefit (80–82). Anderson et al. (80) reported that 81% of individuals undergoing injections for this condition described symptom relief at 6 weeks. At 4-year follow-up, 58% remained asymptomatic, and 33% had complete reoccurrence. If conservative treatment is not effective, surgical release of the first dorsal compartment can be performed (83,84).

## TRIGGER FINGER “STENOSING TENOSYNOVITIS”

Trigger finger or “stenosing tenosynovitis” is a disorder characterized by snapping or locking of the finger (85). This locking

sensation is usually felt at the level of the MCP joint (86). Progression can result in the inability to extend the MCP joint fully. The digit can become mechanically locked in flexion, requiring passive assistance to obtain extension. A similar problem can affect the thumb.

The flexor tendons of the digits (superficialis and profundus) are held in place by five annular and three cruciate ligaments (87) (Fig. 37-5). These pulleys maintain the position of the tendon relative to the MCP, posterior interphalangeal (PIP), and distal interphalangeal (DIP) joints, as well as prevent bow stringing of the tendon when the finger is flexed

**FIGURE 37-5.** Trigger finger. The superficialis and profundus tendons are held in place by five annular and three cruciate ligaments.

(88). By holding the tendon in close association to the joint center of rotation, there is greater angular movement with less tendon excursion.

Trigger finger or stenosing tenosynovitis is a very common condition seen by hand specialists. It is thought to be secondary to a thickening of the A-1 pulley or flexor tendon owing to sheer or compression forces (89,90). Acute conditions demonstrate inflammatory changes in the region of the A-1 pulley. In chronic conditions, no inflammatory changes are noted (91). For this reason, the nomenclature of “stenosing tenosynovitis” has lost favor. Chronic conditions result in degenerative changes consistent with fibrocartilaginous proliferation of the A-1 pulley or tendon. The pathologic thickening results in a disparity of the tendon pulley configuration (92). This size differentiation causes a mechanical locking of the tendon proximal to the A-1 pulley with finger flexion. Once the tendon is locked in the flexed position, the weaker finger extensors have difficulty overcoming the resistance (93). When the stuck tendon does release during extension, there is a painful snapping in the region of the MCP joint.

Trigger finger has been described as having a bimodal age distribution. It is usually seen in children younger than 6 years or adults older than 40 years (94,95). Women are affected more than men (95,96). The thumb of the dominant hand is most commonly affected, followed by the middle and ring fingers (97,98). The symptoms usually consist of a snapping or locking sensation with full flexion of the digit. This sensation is usually painful, but nonpainful conditions have been described. The onset is usually gradual, over several months, but in certain situations can be due to trauma or carpal tunnel release (99,100). The symptoms of locking or clicking phenomena are usually worse in the morning and after repetitive gripping or pinching-type activities (101).

Examination of the finger is usually unremarkable unless reproduction of the locking phenomena can be observed (101,102). Most often, a tendon nodule or crepitus can be felt over the palmar aspect of the MCP joint in the region of the A-1 pulley (86). Grip strength can be diminished secondary to pain. Ligament and neurovascular integrity is normal. No diagnostic tests are confirmatory for this condition. X-rays have not been found to show any abnormality correlated with trigger finger (103). Serologic testing should be done to check for the presence of underlying conditions such as diabetes mellitus, hypertension, and inflammatory arthritis, which are risk factors for trigger finger (101).

Trigger finger is often nothing more than a nuisance. Depending on one's hand usage and occupation, however, a trigger finger can lead to disabling pain. Physical modalities such as ultrasound, iontophoresis, and ice may relieve symptoms (104). Evans et al. (105) reported 73% success in using a flexion-blocking splint at the MCP for 3 weeks. Their protocol also included limiting activities requiring grasp, active flexion or repetitive stress, and hooked-fish exercises. Colbourn et al. (106) confirmed these findings but required 6 weeks of continuous splint usage.

Corticosteroid injections have been reported to be highly efficacious in the treatment of trigger finger (107,108).

Newport et al. (109) reported that one to three injections of local anesthetic and cortisone were associated with resolution or improvement in 77% of 338 fingers. Marks and Gunther (110) reported that 84% of trigger fingers and 92% of trigger thumbs responded to a single injection. This increased to 91% and 97%, respectively, with a second injection. Serious complications such as infection and tendon laceration have not been reported (111).

Surgical intervention has been advocated if injection therapy does not offer benefit. There has been a plethora of surgical information regarding A-1 pulley releases for the treatment of trigger finger. Thorpe (112) reported that of 53 operations, 60.4% were completely successful, and 11.3% had incomplete resolution with persistence of clicking and pain within the first year after surgery.

## FINGER SPRAINS AND STRAINS

The most common injuries of the hand are finger sprains and strain. Typically, these are described as “jammed fingers” because an axial load is placed on the digit when trying to catch a ball, striking the digit against a surface, or falling onto an outstretched hand.

### DIP Joint

To understand the ligamentous and tendinous injuries of the digits, one must first understand the anatomy of the finger joints. The DIP joint is a classic hinged joint with very little radial-ulnar deviation or pronation-supination (Fig. 37-6A, B). This is partly due to the bony configuration, which is bicondylar in shape. Additionally, the radial and ulnar collateral ligaments originate at the center of rotation for DIP flexion and extension and, therefore, remain fairly tight throughout the range of motion of the joint. The volar surface is covered by a thick volar plate, which has a small amount of laxity allowing 40 to 50 degrees of hyperextension. Two tendons cross the DIP joint and terminate at the base of the distal phalanx. On the volar surface lies the termination of the FDP. On the dorsal surface lies the terminal slip of the extensor tendon. These two tendinous structures are the most commonly injured of the DIP joint.

Rupture or fracture avulsion of the terminal extensor tendon causes the distal phalanx to droop in a classic “mallet finger” deformity (113). In this situation, there is unopposed flexion by the FDP and a complete lack of an extensor force. Therefore, the joint is held in flexion. The DIP may still be extended passively and may flex actively against resistance. Typically, this injury occurs with an axial load on the digit directed slightly in a flexion moment. Aside from the characteristic posturing of the joint, x-rays may show a bony avulsion fragment off the proximal dorsal rim of the distal phalanx. At times, the still intact extensor tendon may draw this fragment proximally as far as the midshaft of the middle phalanx. Assuming the joint remains stable (indicated by lack of subluxation on the lateral view x-ray), the treatment is always that of splinting the

**FIGURE 37-6.** A: DIP, lateral view. B: DIP, volar surface.

DIP in slight extension. Although surgical repair is possible, most would argue that this leads inevitably to a stiff DIP joint. Instead, religious splinting of the joint for 6 to 8 weeks most often restores active extension, even with proximal migration of the avulsion fragment. Delayed treatment may require longer splinting periods, and it is possible that conservative treatment may fail. At such times, surgical treatment may be considered, although this rarely results in a mobile joint.

On the flexor surface of the DIP joint, the most common injury is that of rupture of the FDP (114). This is typically called a “jersey finger” because a common mechanism of injury is that of a football player catching the tip of his finger inside the neck of an opponent’s jersey and forcefully flexing the DIP joint against a stronger extension force. X-rays are usually unremarkable and rarely show an avulsion fragment off the proximal volar rim of the distal phalanx. Unlike the common extensor tendon, there is little to stop proximal migration of such an avulsion fragment and of the free end of the profundus tendon from migrating proximally even into the palm. Treatment is surgical, and little is regained by conservative care.

### Proximal Interphalangeal Joint

The ligamentous structure of the PIP joint is almost an exact replica of the DIP joint. The lone exception is that the volar plate has less redundancy than the DIP joint with stout check rein ligaments that extend proximally and prevent hyperextension (Fig. 37-7). Superficial to the PIP joint lies the extensor tendons dorsally, the FDP and the FDS volarly, a number of retinacular ligaments, and the extensor mechanism that coordinates PIP and DIP movements. Because of the multiple tendonous and ligamentous structures that cross the PIP joint and the tight stout volar plate, the PIP joint is much more likely to develop stiffness after trauma or surgery than the other digital joints.

The most common injury to the PIP joint is a ligamentous sprain or strain of the volar plate, collateral ligaments, or accessory ligaments. The most common fracture of the digit is a chip fracture off the proximal volar lip of the middle phalanx (115). These injuries usually result from an axial load to the digit (or “jam”) causing dorsal subluxation of the middle phalanx on the proximal phalanx or more simply,

**FIGURE 37-7.** PIP. crl, check rein ligament.

hyperextension and radial or ulnar deviation. In almost all cases, the treatment is that of buddy taping the involved digit with the adjacent digit. Tape is applied proximally and distally to the PIP joint. A small amount of cotton is placed between the digits to prevent skin maceration. Buddy taping allows for protective active-assisted range of motion of the involved

joint while preventing hyperextension as well as radial or ulnar deviation.

The exception to this rule is when there is evidence of instability. Instability would be indicated by subluxation of the PIP joint seen on the lateral view of the digit. Some authors would also argue that an intra-articular fracture involving greater than one third to one half of the joint space would also indicate an unstable joint and necessitate surgical intervention (115). On examination, instability may also be evident by an inability to extend the joint actively or by the joint “opening up” or showing an unexpected amount of passive movement on hyperextension plus either radial or ulnar deviation.

Assuming there is no large fracture fragment, these unstable PIP sprains are treated with a dorsal extension-blocking splint (116). Typically, the joint will sublux on extension and reduce in flexion. Ideally, the joint is examined under fluoroscopy or with lateral x-rays in various degrees of flexion. One must establish the point of extension at which the joint subluxes. A dorsal-blocking splint is then fabricated to prevent extension past this point. Therefore, the joint is allowed to move within the arc of motion where it remains in reduction. This prevents the severe stiffness of static splinting while it allows healing. The joint is then examined radiographically every 1 to 2 weeks, and the blocking splint is repositioned to allow greater extension as the joint stays reduced in greater degrees of extension. Often, the joint is also buddy taped to the adjacent digit within the blocking splint to promote range of motion.

There is almost never an indication for static postinjury splinting of the PIP joint except after surgery. The PIP joint has such a tendency toward stiffness that it is almost better to

**FIGURE 37-8.** A: MDP, lateral view. B: MCP, volar surface.

risk instability by too little immobilization than to develop stiffness by too much immobilization.

### MCP Joint

The MCP joint geometry is very different from the other finger joints. Instead of a bicondylar formation of the interphalangeal joints, the head of the metacarpal bone has a dome shape (Fig. 37-8A, B). This rounded surface allows for radial and ulnar deviation in addition to flexion and extension as well as minimal pronation and supination. This extensive range of motion makes the joint inherently less stable. Although the metacarpal head is most domed on the extensor surface, it flattens out in the flexor surface. The collateral ligaments also originate dorsal to the metacarpal head's center of rotation, thus tightening in flexion. These two geometric characteristics make the MCP joint more stable in flexion than in extension.

There are two common mechanisms for MCP sprains. One mechanism of injury is to catch the joint in 90 degrees of flexion when the collateral ligaments are tightened. At this point, a radial or ulnar stress to the digit may injure one of the collateral ligaments. A second mechanism is that of a fall during which the victim lands on a clenched fist. This drives the proximal phalanx proximally along the palmar surface of the metacarpal shaft. This may injure the volar plate plus one or both of the collateral ligaments. Many MCP sprains produce an unstable joint. As with the PIP joint, an unstable joint is seen with a lateral view x-ray, which shows a dorsal subluxation of the metacarpal head. An unstable MCP joint eventually leads to ulnar deviation of the digit as would otherwise be seen in inflammatory arthritis.

Both of these MCP strains are treated with extensive immobilization. A radial- or ulnar-based hand gauntlet splint may be fabricated extending to the index and long or ring and small proximal phalanges. The two proximal phalanges are held together with a small strap. The MCP joint is held in neutral position or 20 degrees of flexion. Expect to splint for 8 to 12 weeks or even longer. An unstable MCP joint is an indication for surgical intervention.

### KIENBÖCK'S DISEASE

Kienböck's disease is avascular necrosis of the lunate. According to early definitions, this is an atraumatic event. However, the etiology may consist of a combination of factors, including vascular and skeletal variations as well as trauma and repetitive loading (117). The typical symptom is that of middorsal wrist pain with point tenderness to palpation over the dorsum of the lunate. In the early stage of the disease, x-rays may be normal. Three-phase bone scans at this stage show an area of decreased uptake at the lunate in all phases of the scan, indicating a lack of blood flow. Magnetic resonance imaging (MRI) shows a decreased T1 and T2 signal at the lunate or what appears to be a black lunate (118). As the condition progresses, the x-rays will first show cystic

changes followed by progressive collapse and sclerosis. At these later stages, the bone scan shows increased uptake at the lunate, indicating further bony healing of the fractures of collapse.

Most authors suggest surgery for Kienböck's disease; however, conservative treatment with cast immobilization has been used in the acute or early stages (119). Many surgical procedures have been described, including joint leveling (either shortening the radius or lengthening the ulna) (120), various intercarpal fusions (121), silastic arthroplasty (122), or vascularized bone grafts (123). Most importantly, Kienböck's should be treated immediately to limit further compression of the lunate and collapse of the carpus.

### DUPUYTREN'S DISEASE

Dupuytren's contracture is a thickening of the palmar fascia. It affects men 7 to 15 times more than women and is thought to be an autosomal dominant inheritance, with variable penetration (124,125). Usually, Dupuytren's affects whites of northern European descent, and its prevalence increases with age (126,127). The fascial thickening progresses ulnarly to radially and can result in flexion deformities of the MCP, PIP, and, occasionally, the DIP joint.

Dupuytren's contracture is a benign hypertrophy of the fascia. It usually begins insidiously as small imperceptible nodules in the area of the palmar crease. It can progress to thick cords that form along the fascia tension lines of the palm (128). The underlying tendons, synovial sheaths, and skin layers are not affected (129).

The pathophysiology of Dupuytren's is not fully understood; there is, however, a higher incidence in alcoholic, diabetic, and epileptic patients, and there is thought to be a correlation with tobacco use (130). A clear association between Dupuytren's and trauma or work activities has not been identified (131). The palmar fascia thickening is caused by an abnormal proliferation of fibroblasts (132). This proliferation is closely correlated with that observed in scar formation and healing. Three stages in the nodule and cord formation have been described. The first stage is proliferation. During this stage, the numbers of myofibroblasts within the palmar fascia spontaneously increase. The second stage is involution, when the myofibroblasts align along the tension lines of the palm and digits. The fascia enlarges owing to contraction of the myofibroblastic activity. In the third phase, the myofibroblasts resolve, leaving contracting collagen, which is perceived as nodules and matures into cords (133).

Many individuals with this condition are unaware of its presence. Usually, it is first noted when the palmar nodules and cords become tender with pressure (128). Activities that require frequent or strenuous gripping often result in tenderness near the nodules or cords. The palmar fascia of the small finger is the most commonly affected in 70% of individuals with this condition (134). This is typically followed in succession by the fascia of the ring, middle, thumb, and index fingers. Other pathologic processes with a similar

**FIGURE 37-9.** Dupuytren's nodules. Hypertrophic skin changes and cord formations are classic findings in Dupuytren's disease.

presentation include intrinsic joint contractures, palmar ganglion inclusion cysts, stenosing tenosynovitis, occupational hyperkeratosis, callous formation, soft-tissue giant cell tumors, epithelial sarcomas, and early changes of rheumatoid arthritis (128).

Dupuytren's contracture is a clinical diagnosis that is made upon exclusion of the above conditions. The hallmark of clinical evaluation is the palpable nodules and cords in the palmar fascia, most notably in the small finger. Hypertrophic changes of the skin are also appreciated (Fig. 37-9). Joint deformity, including flexion contractures of the MCP, PIP, and DIP, is usually present in advanced conditions. Transverse or webspace contractures may also occur. These contractures can result in significant functional limitations necessitating treatment.

Multiple treatment regimes for this condition have been described, including splinting, radiation, and use of disulfides, vitamin E, anti-gout medications, physical therapy, and ultrasonic therapy (127). These therapies have shown minimal effectiveness (135). Treatment of advanced Dupuytren's is surgical fasciectomy. This is recommended when the patient can no longer perform a "tabletop test" (136). In this test, the individual places the palm on a flat surface and attempts to extend the involved finger actively. A positive test is noted if the MCP joint cannot be placed flat against the surface. This usually correlates with a greater than 30-degree fixed flexion contracture of the MCP joint. The goal of surgery is to restore function, not to cure the disease (136).

Recently, there has been a great deal of interest in percutaneous or enzymatic fasciotomies as an alternative to surgical fasciectomy. Hurst and Badalamente (137) have demonstrated that by injecting collagenase into the fibrous cords, joint contractures can be improved. They report that 90% enjoyed excellent results at an average of 9-month follow-up. Although no long-term studies have been completed, this procedure does offer promise.

Postoperative surgical rehabilitation is extremely important following fasciectomy, with concentration on maintaining skin integrity, restoration of joint range of motion, and

overall improvement of function (138,139). Despite surgical treatment, this condition can be quite recalcitrant, and reoccurrence rates range from 28% to 80% (134).

## COMPLEX REGIONAL PAIN SYNDROME

Complex regional pain syndrome (CRPS; previously known as reflex sympathetic dystrophy or RSD) is a neuropathic pain syndrome characterized by autonomic dysfunction and severe pain that may lead to crippling contractures of the limbs. Mitchell first described CRPS during the American Civil War when he observed wounded veterans who had burning pain in an injured limb (140). Since that time, many labels have applied to what is now called CRPS or some subset of CRPS. The most common of these are RSD, causalgia (minor and major), algodystrophy, shoulder-hand syndrome, and Sudeck's atrophy. In 1993, at the meeting of the International Association for the Study of Pain (IASP), a task force proposed a unifying classification for these syndromes (141). The task force proposed a definition based on four criteria (Table 37-4).

The IASP proposed dividing the classification into types I and II, with type II being characterized also by injury to a peripheral nerve.

The primary treatment for CRPS is the use of physical therapeutics (142). In treating CRPS, one follows the classic order of rehabilitation beginning with pain and edema control, followed by range of motion, then strengthening, and then function. It is important to convey to the patient that immobilization is not an effective treatment for the pain and swelling; in fact, it may be instrumental in the pathogenesis and chronicity of the process.

Edema control entails elevation, decongestive massage, and various forms of compressive wrapping or garments. Pain control may be difficult using physical modalities alone. However, physical modalities should be the first line of defense. Contrast baths, Fluidotherapy, transcutaneous electrical nerve stimulation (TENS), and desensitization may be used before and after therapy session or exercise. If these are unsuccessful in adequately controlling the pain to the point at which therapy can be progressed, then one may consider further pain-relieving measures. Typical oral medications that may be used are tramadol, gabapentin, amitriptyline, and various  $\alpha_1$ -blockers. In about half of all cases, further augmentation of analgesia may be attained by injections such as stellate ganglion blocks. One may also use injections such as intravenous regional blocks, axillary blocks, and cervical epidural injections. These blocks may provide temporary pain relief, enabling the patient to begin more aggressive hand therapy. Once pain is controlled to the level that patients can tolerate therapy, then one may begin exercises.

The next goal of CRPS treatment is to restore normal range of motion. Often, the enduring disabilities resulting from CRPS are hand contractures. Gentle active or active-assisted range of motion should begin in a pain-free fashion. Any advancement in therapy should proceed slowly and carefully, keeping

**TABLE 37.4** Proposed Clinical Diagnostic Criteria for CRPS

<b>General definition of the syndrome:</b>	
CRPS describes an array of painful conditions that are characterized by a continuing (spontaneous and/or evoked) regional pain that is seemingly disproportionate in time or degree to the usual course of any known trauma or other lesion. The pain is regional (not in a specific nerve territory or dermatome) and usually has a distal predominance of abnormal sensory, motor, sudomotor, vasomotor, and/or trophic findings. The syndrome shows variable progression over time.	
<b>To make the clinical diagnosis, the following criteria must be met:</b>	
1. Continuing pain, which is disproportionate to any inciting event	
2. Must report at least one symptom in <i>three of the four</i> following categories:	
<b>Sensory:</b> Reports of hyperesthesia and/or allodynia	
<b>Vasomotor:</b> Reports of temperature asymmetry and/or skin color changes and/or skin color asymmetry	
<b>Sudomotor/Edema:</b> Reports of edema and/or sweating changes and/or sweating asymmetry	
<b>Motor/Trophic:</b> Reports of decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nail, skin)	
3. Must display at least one sign at time of evaluation in <i>two or more</i> of the following categories:	
<b>Sensory:</b> Evidence of hyperalgesia (to pinprick) and/or allodynia (to light touch and/or temperature sensation and/or deep somatic pressure and/or joint movement)	
<b>Vasomotor:</b> Evidence of temperature asymmetry ( $>1^{\circ}\text{C}$ ) and/or skin color changes and/or asymmetry	
<b>Sudomotor/Edema:</b> Evidence of edema and/or sweating changes and/or sweating asymmetry	
<b>Motor/Trophic:</b> Evidence of decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nail, skin)	
4. There is no other diagnosis that better explains the signs and symptoms	

For *research* purposes, diagnostic decision rule should be at least one symptom in *all four* symptom categories and at least one sign (observed at evaluation) in two or more sign categories.

in mind that an overly aggressive approach may increase pain and swelling, which would be counterproductive.

When recognized early and treated carefully, CRPS generally runs its course in 6 to 12 months with complete or nearly complete recovery. About 5% of cases may turn into chronic CRPS with ongoing issues of pain, dysfunction, and disability. These patients may be on long-term pain medications or often are severely disabled by pain, contractures, or both. Reviews of current thinking about the pathophysiology and management of CRPS are available (143,144).

## FOCAL DYSTONIA

Writer's cramp and musician's cramp are both focal dystonias that affect a discreet anatomical area. They are characterized by disabling cramps, contractions, or spasms during specific activities (145). When not so engaged, the hand appears and functions normally. The flexors are more commonly involved than the extensors. Among the flexors, the FDS, FDP, FPL, and the lumbricals may be involved. The extensor pollicis longus, extensor indicis, and digitorum communis may be involved among the extensors. Dystonia may occur sporadically in the population or may be genetically transmitted. The gene for early onset dystonia (DYT1) has been sequenced. Approximately 10% of people with dystonia have a family history of tremor or dystonia (146). Others report that a higher percentage of those affected have a family history of dystonia (147).

The incidence of writer's cramp is reported to be 2.7 per million in Rochester, MN (148). It tends to affect male young adults. It is usually idiopathic and not a result of overt trauma, although it may follow a traumatic episode. Patients frequently have mirror dystonia, demonstrated by inducing the writer's cramp in the dominant hand even when attempting to write with the nondominant (146). Focal dystonias tend to remain focal and do not become generalized dystonias over time.

The pathophysiology of dystonia is not entirely understood. However, there seems to be some evidence for abnormalities in the basal ganglia (145) or problems with cortical organization (149). Electrodiagnostic studies show a co-contraction of muscle and a loss of alternation of agonist/antagonist muscle contractions. There are prolonged bursts of muscle contractions and overflow contraction seen in those muscles not activated by the motor task (150). There is a neurophysiologic defect in the ability to produce and process neurotransmitters, including (a) gamma-aminobutyric acid (*GABA*), an inhibitory substance that helps the brain maintain muscle control; (b) dopamine, an inhibitory chemical that influences the brain's control of movement; and (c) acetylcholine, norepinephrine, and serotonin.

Treatments have been aimed at correcting these possible pathological situations. GABA-regulating drugs such as the muscle relaxants diazepam, lorazepam, clonazepam, and baclofen have been used with modest success. Deep brain stimulation (151) and proprioceptive retraining (152,153) have anecdotally been reported as successful.

Currently, it appears that botulinum toxin offers the most reliable relief for focal dystonia, with minimal risk (154). Selection of patients for this treatment should include a careful neuromusculoskeletal examination. Once the diagnosis of focal dystonia is confirmed, the selection of the muscles that are to be injected is made. Often, these muscles can be identified by observing the patient performing the inciting tasks. However, it may be useful to use EMG to identify all those that are activated, including the deeper muscles that may not be obvious clinically. A starting dose of 2.5 U of botulinum toxin type A for small muscles and up to 50 U for larger muscles is usually injected. The botulinum toxin can be diluted into a larger volume for ease of administration. The use of EMG or ultrasound to guide injections increases the accuracy of correctly identifying the contracting muscles (155). The benefits are usually seen within 1 week and may last for a few months. Repeated injections are safe and are often needed to sustain the benefits (156). A secondary effect of botulinum type A injections is an associated muscle weakness, which may respond to muscle strengthening. A small proportion of patients receiving continued treatment may develop antibodies to type A. These patients may respond to botulinum type B or F (157,158).

# Foot Disorders

## INTRODUCTION

Foot pain and problems are common among people of all ages. The prevalence has been reported as 15% to 40%, depending on the demographic distribution of the patient population (1–3). Foot disorders in the younger age group are frequently the result of trauma or congenital anomalies, and require a different approach to management than the elderly adult. The published literature on foot pain in the adult/aged population is quite extensive and indicates that it affects between 20% and 30% of community-dwelling elders (4). Some studies have shown that foot pain is associated with decreased ability to perform activities of daily living (5), problems with balance and gait (6–8) and increased risk of falls. Others have not found that to be the case (9). *In fact, they reported that while there are a significant number of foot problems facing the elderly, only plantar fasciitis and a pes cavus foot profile are associated with functional foot problems.* Another study has shown that elders with rheumatoid arthritis and who have significant foot pain are more likely to report back, hip, hand, and wrist pain. They also have pes planus and loss of motion in the ankle joint (10).

While it is useful to understand the issues of prevalence of foot pain and problems, and their associations with function, these must be understood within the context of the specific population (e.g., diagnostic group, age, etc.) of interest.

## EXAMINATION

### Physical Examination

The foot examination begins with an assessment of all the segments of the lower extremity. This should include measures of muscle strength, range of motion (ROM), alignment, stride characteristics, neurological examination (e.g., sensation, vibration and proprioception), vascular status, skin and nails, and review of shoe selection and wear patterns.

## ANATOMY

Examination of the foot is challenging because of its complex anatomy, its biomechanical properties, and its function. This section attempts to describe important anatomic information that will enable the clinician to understand the affected

anatomic site, but the reader is referred to books on anatomy, which present a more in-depth review (11–13).

Each foot is composed of 26 bones and 55 joints with muscle attachments that have their origin either within the foot or from the anatomical structures above the ankle. It is easier, therefore, to divide the foot into sections: the forefoot, midfoot, and rearfoot-ankle complex. This simplifies the examination process and provides the foundation necessary to understand biomechanical principles. The forefoot consists of 5 metatarsals and 14 phalanges constituting the five digits. The midfoot includes three cuneiform, cuboid, and navicular. The rearfoot-ankle complex is composed of the talus, calcaneus, and distal ends of the tibia and fibula (Fig. 38-1). These three divisions form a tenuous interrelationship that can easily be disrupted, resulting in dysfunction and pathology.

The hallux contains two phalanges, and the remaining four digits contain three each. The hallux has one joint: the interphalangeal joint. The lesser digits form the proximal and distal interphalangeal joints. There is a tendency for the intermediate and distal phalanges of the fifth toe to be fused together. The first metatarsal head distally articulates on the plantar surface with the tibial and fibula sesamoid bones, which are within the flexor hallucis brevis tendon. There are three cuneiforms that articulate with the base of metatarsals one through three. The cuboid articulates with the fourth and fifth metatarsal bases. The five metatarsals, along with the three cuneiforms and cuboid, form Lisfranc's joint. Injury to this joint often is missed at initial presentation with significant associated morbidity. The keystone of this joint is the second metatarsal cuneiform articulation. The base of the fifth metatarsal, along with the lateral styloid process, serves as the insertion site of the peroneal brevis tendon. Injuries to the base of the fifth metatarsal and the styloid process are common, especially after inversion injuries of the ankle. The configuration of the articulation between the metatarsals, cuneiforms, and cuboid helps form the transverse metatarsal arch. Proximally, the cuneiforms articulate with the navicular, and laterally, the cuboid articulates with the navicular and lateral cuneiform. Medially, on the navicular, there is an enlarged tuberosity that serves as part of the insertion points of the tibialis posterior tendon. The navicular and cuboid proximally articulate with the talus and calcaneus, respectively, forming themidtarsal joint. The calcaneus is the largest bone of the foot. It functions as a major weight-bearing bone and serves as the insertion site posteriorly for the Achilles tendon. Many of the intrinsic muscles

**FIGURE 38-1.** Osseous anatomy of the foot.

arise from its plantar tubercles. The calcaneus is composed primarily of cancellous bone. Its dorsal surface articulates with the talus through three articulating surfaces—anterior, middle, and posterior—called facets. This forms the subtalar joint. A tunnel forms across the middle facet that begins laterally as the sinus tarsi and ends medially as the tarsal canal. Medially, the calcaneus forms a projection called the *sustentaculum tali* that provides a groove for the flexor hallucis longus tendon. The talus acts as a torque converter that connects the leg to the foot. It is almost completely covered with cartilage and has no muscular or tendinous attachments. Anatomically, it is divided into the head, neck, and body. The body, through its superior trochlear surface, the talar dome, forms the ankle joint with the distal extensions of the fibula and tibia, termed *malleoli*. The trochlear surface is wider anteriorly, which provides increased stability of the ankle in dorsiflexion. Plantar flexion of the ankle results in articulation, with the narrower portion of the posterior trochlear surface, resulting in intrinsic instability associated with the common ankle sprain. Fractures of the talus at its neck are associated with increased frequency of avascular necrosis owing to its tenuous but generous blood supply. Fractures of the talar body often result in posttraumatic arthritis. Posteriorly, the talus forms two tubercles—medial and lateral. The lateral tubercle has been called *Steida's process*. Sometimes, the lateral tubercle fails to ossify completely; it is then termed the *os trigonum*.

Blood supply to the foot is the result of branches from the popliteal artery. The popliteal artery divides into the anterior tibial, posterior tibial, and peroneal arteries. The branches of these arteries are noted in Table 38-1. The venous drainage system of the foot is divided into deep and superficial segments. The lesser saphenous and greater saphenous veins form the superficial system, whereas the deep venous arch provides the deep drainage.

**TABLE 38.1** Branches of the Anterior Tibial, Posterior Tibial, and Peroneal Arteries

Artery	Branches
Anterior tibial	Anterior medial and lateral malleolar Medial and lateral tarsal Dorsal pedis Arcuate, first dorsal and plantar metatarsal
Posterior tibial	Posterior medial malleolar Medial and lateral plantar
Peroneal	Posterior lateral malleolar Perforating peroneal

Motor and sensory nerves to the foot arise from branches of the sciatic nerve. The sciatic nerve divides into the tibial nerve, common peroneal nerve, and sural nerve. The common peroneal nerve divides into the superficial and deep peroneal nerves. They provide sensory input to the dorsal aspect of the foot and digits. The sural nerve innervates the lateral aspect of the foot. The saphenous nerve innervates the medial aspect of the foot and is a branch of the femoral nerve. The motor component of the peroneal nerve innervates the peroneus longus, peroneus brevis, extensor hallucis longus, extensor digitorum longus and brevis, tibialis anterior, and peroneus tertius. The tibial nerve divides into the medial and lateral plantar nerves. They provide sensory and motor innervation to the plantar aspect of the foot.

The muscles of the foot are divided into extrinsic and intrinsic groups (Figs. 38-2 and 38-3). The extrinsic muscles arise in the leg and insert into the foot and are held in place by various retinacula as they enter the foot. They are divided into four compartments: superficial posterior, deep posterior, lateral, and anterior (Table 38-2). The intrinsic muscles of the foot are divided into dorsal and plantar groups. The plantar muscles are divided into four layers, with the first layer being the most posterior or superficial and the fourth layer the most anterior or deep (Table 38-3).

### Functional Anatomy

The foot is divided into three functional units or parts: the hindfoot (talus and calcaneus and its attachments) provides the foot with stability; the midfoot (navicular, cuboid, cuneiforms, Lisfranc's and Chopart's joints) provides both sagittal and frontal plane motion; and the forefoot (metatarsals and phalanges) permits push-off. The ligamentous structures establish and preserve the longitudinal arch, the intermetatarsal transverse arch, the position of the sesamoids, and stability of the ankle mortise.

**FIGURE 38-2.** Lateral view of the intrinsic and extrinsic muscles of the foot.

The subtalar joint is composed of the talus and calcaneus. The bones articulate at the posterior, middle, and anterior facets. The joint is responsible for triplane motion, primarily pronation and supination. There is 20 degrees of inversion to 10 degrees of eversion to the subtalar joint. In closed kinetic chain pronation, the calcaneus everts, with adduction

**TABLE 38.2** Extrinsic Muscles of the Foot

Extrinsic Muscle Groups	Muscles	Function
Superficial posterior	Gastrocnemius	Plantar flexion
	Soleus	Plantar flexion
Deep posterior	Tibialis posterior	Plantar flexion
	Flexor digitorum longus	Plantar flexion
	Flexor hallucis longus	Plantar flexion
Lateral	Peroneus longus	Eversion
	Peroneus brevis	Eversion
Anterior	Tibialis anterior	Dorsiflexion
	Extensor hallucis longus	Dorsiflexion
	Extensor digitorum longus	Dorsiflexion
	Peroneus tertius	Dorsiflexion

**FIGURE 38-3.** Anterior view of the intrinsic and extrinsic muscles of the foot.

**TABLE 38.3** Intrinsic Muscles of the Foot

Intrinsic Muscle Groups	Muscle	Function
Dorsal	Extensor digitorum brevis	Extension of toes
	Extensor hallucis brevis	Extension of hallux
Plantar Layer 1	Abductor hallucis	Abduction of hallux
	Flexor digitorum brevis	Flexion of toes
	Abductor digiti minimi pedis	Abduction of fifth toe
Layer 2	Quadratus plantae	Helps in flexion of toes
	Lumbrices (4)	Flexion MTPJ/extension IPJ
	Tendons of long flexors	
Layer 3	Flexor hallucis brevis	Flexion of hallux
	Adductor hallucis	Adduction of hallux
	Flexor digiti minimi brevis	Flexion of fifth toe
Layer 4	Plantar interossei	Adduction of toes
	Dorsal interossei	Abduction of toes
	Tendons of peroneal longus and tibialis posterior	

IPJ, interphalangeal joint; MTPJ, metatarsal phalangeal joint.

**FIGURE 38-4.** Abducted stance with “too-many-toes sign.”

and plantar flexion of the talus. The opposite is true for closed kinetic supination (Fig. 38-4).

The position of the subtalar joint dictates the position of the midtarsal joint. When the subtalar joint supinates, the arch raises the forefoot, and the foot becomes more rigid. The midtarsal joint “locks.” When there is subtalar joint pronation, the midtarsal “unlocks” and becomes less rigid. The foot becomes a mobile adaptor, allowing for increased motion to take place to accommodate for varying terrain.

The midtarsal joint is made up of the calcaneocuboid and talonavicular joints. The midtarsal joint has two axes of motion: the longitudinal and oblique axes. The longitudinal axis inverts and everts the forefoot while pronation or supination occurs. The oblique axis allows for adduction, abduction, plantar flexion, and dorsiflexion of the foot.

### Physical Examination of the Foot

ROM assessment of the lower extremity is important because absence of normal range has functionally important sequelae. For example, a tight Achilles tendon, which limits ankle dorsiflexion, creates a force anterior to the axis of the ankle, which results in pronation, or collapse of the medial column. Limitation of hallux dorsiflexion to less than 25 degrees creates an impediment to forefoot push-off.

When testing ROM for the ankle, there should be at least 10 degrees of dorsiflexion with 45 degrees of plantar flexion. When testing the range of dorsiflexion, the examiner should hold the foot medially. This keeps the midtarsal joint locked, and a more accurate measurement can be achieved. Dorsiflexion is measured with the knee extended and flexed. When the knee is flexed, there is more dorsiflexion of the ankle because of the “unlocking” of the gastrocnemius complex. The ankle motion should be smooth and unrestricted. The subtalar joint should measure 20 degrees of inversion and 10 degrees of eversion. This can be measured with the patient in the prone position. The heel is bisected in half, and the examiner can then use a tractograph and invert and evert the foot for the

measurement. The metatarsophalangeal joints, the distal and proximal interphalangeal joints of the lesser toes, and the interphalangeal joint of the hallux should have smooth and unrestricted dorsiflexion and plantar flexion.

Muscle strength testing provides important information about whether the foot is likely to be supported in stance (static) and dynamic phases of gait.

Support of the foot in stance comes from the ligaments and plantar fascia, which stabilize the longitudinal arch and the intrinsic muscles of the foot. The creation and establishment of the longitudinal arch in the dynamic phase depend on the posterior tibialis and intrinsic and extrinsic muscles of the foot. The gastrocnemius provides propulsion through sagittal plane motion at the ankle. Weakness in these structures may help explain an apopulsive gait or instability during stance.

Determination of static alignment of the foot provides important information about how the foot will contact the ground. The preferred position is that the foot should be parallel to the floor. If ligamentous structures are intact, ROM abnormality or muscle imbalance is likely to explain alignment problems. Examination demonstrates possible forefoot varus or valgus deformity. This is performed with the patient in the prone position with the subtalar joint neutral.

The feet should be evaluated in the standing position, and the arch *height* is evaluated as flat, low, normal, or high, based on the navicular position. The angle of the talus measured radiographically may be used to assess arch height. Bisecting the Achilles tendon will demonstrate whether the calcaneus is everted or inverted with respect to the midline. A varus rear-foot generally causes pressure to the posterosuperior lateral aspect of the calcaneus. A bone spur can develop in this area and cause pain. This is known as a Haglund’s deformity. Severe calcaneoeversion can cause a lateral impingement and pain to palpation below the lateral malleolus.

The vascular exam will evaluate peripheral pulses in the foot. Dorsally, there is a dorsalis pedis pulse, and medially a posterior tibial pulse. If one cannot feel a pulse and there is questionable vascular compromise, the physician can order further vascular testing such as noninvasive arterial Doppler. This exam would be beneficial when dealing with lower extremity ulcerations. Capillary filling time is tested and should be within 2 seconds. Press the distal tip of the digit and determine how fast the digit fills up with blood. Another area of testing would be for dependent rubor. Dangle the foot off the examining table and see if the foot becomes more red or purple. If this occurs, there may be pathology to the venous system of the lower extremity. Any varicosities should also be noted to the lower extremities, as well as chronic swelling. Patients with brawny edema from venous stasis disease may develop ulcerations to the medial lower leg or ankle.

The neurological exam will test deep tendon reflexes, ankle clonus, Babinski’s sign, sharp and dull discrimination, as well as vibratory sense and proprioception. Patients who are neuropathic have diminished sensation, vibratory sense,

and lack of proprioception. It is useful to test for protective sensation using Semmes-Weinstein filaments. Those who cannot feel the touch of a nylon filament 5 mm in diameter are at significant risk for ulceration. They are at risk for ulcerations because they lack sensation to the foot and do not feel the pressure caused by a foreign body, minor cut, abrasions from poorly fitted shoes, or thickened calluses.

Examination of the skin indicates where pressure points are. Callosities are in areas of high pressure and often need to be relieved.

## DIAGNOSTIC TESTING

The proper selection of imaging techniques enhances the ability to diagnose foot disorders. When dealing with foot pain, one should be knowledgeable about selecting from among plain radiographs, computerized tomography, magnetic resonant imaging (MRI), and ultrasound. The application of diagnostic ultrasound has offered clinicians and clinical investigators opportunities to increase the sensitivity and specificity of patient evaluation and assessment of treatment outcomes.

A good review of which diagnostic tools are best applied to which clinical conditions is available for the reader (14). A summary table of recommendations (see Table 38-1) is given.

Ultrasound has recently received attention because of its usefulness in clinical settings. Sonography has been shown to provide valuable information about soft tissue, including muscle, fascia, tendon, blood vessels, and nerves. Ultrasound is convenient, low cost, and low risk and may be particularly useful in helping to diagnose and follow problems associated with plantar fasciitis and posterior tibialis tendon dysfunction, significant clinical problems (14,15).

## BIOMECHANICS

Foot motion depends on intrinsic and extrinsic muscles that are divided into four compartments (see Table 38-2). These muscles produce sagittal, frontal, and transverse plane motion.

To understand foot biomechanics, the physician must be proficient in the terms used to describe the motion and position of the foot. A list of terms commonly used follows:

*Abduction*: movement of the foot away from the midline of the body

*Adduction*: movement of the foot toward the midline of the body

*Eversion*: turning inward of the feet with the soles pointing away from each other

*Inversion*: turning inward of the feet with the soles pointing toward each other

*Dorsiflexion*: motion whereby the distal end of the foot moves toward the tibia

*Plantar flexion*: motion occurring to the foot whereby the distal end of the foot moves away from the tibia

*Pronation*: triplane motion of the foot in the direction of abduction, eversion, and dorsiflexion

*Supination*: triplane motion of the foot in the direction of adduction, inversion, and plantar flexion

*Subtalar joint*: point at which the normal foot is neither inverted nor everted

*Neutral position*: from the floor during stance; clinically, whereby the posterior aspect of the calcaneus lines up with the lower one third of the leg

*Forefoot varus*: inversion to the plantar surface of the forefoot with the subtalar joint neutral and the midtarsal joint pronated; this is a congenital bony deformity

*Forefoot valgus*: eversion to the plantar surface of the forefoot when the subtalar joint is neutral and the midtarsal joint is pronated; the plane of the metatarsals are everted with the first metatarsal lower than the fifth metatarsal; the first metatarsal may be flexible or rigid; this is a congenital bony deformity

*Rearfoot varus*: inverted position of the sagittal plane and the plantar surface of the calcaneus to the weight-bearing surface with the subtalar joint in the neutral position and the body standing in normal base of gait (10 degrees to 15 degrees of abduction)

*Rearfoot valgus*: the sagittal plane of the posterior and plantar surface of the calcaneus are everted to the weight-bearing surface when the subtalar joint is in neutral position while the body is standing in base of gait

Often, with increased subtalar joint pronation, the foot becomes hypermobile, and increased stress and strain are placed on the lower extremities. A functional valgus occurs at the knee, causing increased stress to the medial aspect of the knee. Hyperpronation causes increased strain on the plantar fascia, causing a pull on the origin of the fascia of the calcaneus. Patients are predisposed to bunions, hammertoes, and postural fatigue with increased subtalar joint pronation. Posterior tibial and Achilles tendinitis can occur with a hypermobile foot because of the increased stretching to the tendon.

A supinated foot or high-arched foot is much more rigid. This type of foot structure predisposes the patient to lateral ankle sprains, lateral Achilles tendinitis, claw toes (flexion deformity at the proximal and distal interphalangeal joints), increased incidence of avulsion fractures to the base of the fifth metatarsal, peroneal subluxation, metatarsalgia, and sesamoid pain or fractures.

## MECHANICAL DYSFUNCTION

### Posterior Tibialis Tendinitis

#### Anatomy and Pathomechanics

The posterior tibial tendon has its origin from the lateral posterior aspect of the tibia, medial aspect of the body of the fibula, and interosseous membrane of the leg (16). The tendon courses under the medial malleolus and into the foot, with

most of the tendon inserting into the navicular tuberosity. The remaining smaller slips of the tendon insert into all tarsal bones except the talus.

The posterior tibial tendon is a plantar flexor and invertor of the foot and a strong supinator of the subtalar and midtarsal joints. The tendon dynamically supports the medial longitudinal arch (17). The peroneus brevis tendon is the antagonistic tendon to the posterior tibial tendon (18), which is an adductor at the level of the midtarsal joint (19).

When there is weakness of the posterior tibial tendon, the foot becomes more abducted because of the overpowering effect of the peroneus brevis (20). When the posterior tibial tendon weakens, the midtarsal joint does not lock, causing increased pronation at the subtalar joint. In time, the medial longitudinal arch collapses, and there is increased shock at the rearfoot, causing a decrease in the propulsive activity of the foot (19).

### Etiology

Posterior tibial tendon ruptures may be traumatic or degenerative in nature. Acute traumatic ruptures are not common, but may occur from puncture wounds, lacerations to the medial ankle (21), and severe eversion ankle sprains (22). Most cases of dysfunction are degenerative (16), such as inflammatory arthritis (23). Diabetes mellitus, obesity, and prior local steroid exposure have been known to cause a degenerative process to the tendon (14). Tendon hypovascularity at the midportion of the tendon just distal to the medial malleolus has been known to cause ruptures to the posterior tibial tendon (14). Abnormal biomechanical forces (equinus, pes valgus) may cause chronic tenosynovitis and weakening of the posterior tibial tendon (15).

A classification system for dysfunctional posterior tibial tendon etiologies has been formulated by Mueller and is based on four categories (19). Type I is a direct rupture due to direct injury to the tendon. Type II is a result of a systemic disease such as diabetes or inflammatory arthritis. Type III is idiopathic or possibly degenerative. Type IV is functional and may be related to severe pronation or stretching of the tendon.

### Clinical Findings

The clinical concerns of the patient may depend on the chronicity of the deformity. In the acute stage, there is swelling and pain along the course of the posterior tibial tendon. The patient may experience the symptoms as an ankle injury (16). In the chronic stage, the patient notices a change in the appearance of the foot. There may be a collapse of the arch, or “too many toes” sign, whereby the toes are pointing outward as the patient is seen from behind (see Fig. 38-4). The patient’s gait becomes increasingly apopulsive, with limited heel lift and toe off. There is excessive wear on the medial aspect of the last of the shoe. The patient demonstrates little or no inversion power with resistance. There may be a palpable gap in the tendon itself. It is our opinion that the tear is most noticeable just proximal and posterior to the medial malleolus. Jahss described tears occurring about 1½ in. proximal to the navicular (24). In the advanced chronic patient, there may be pain of the lateral

foot and ankle, specifically in the sinus tarsi. There may be lateral ankle impingement with involvement of the calcaneofibular ligament, creating an ankle valgus deformity. A long-standing valgus deformity of the ankle can produce a valgus force on the knees, creating pain and deformity to the knees. In the chronic patient, there might be crepitus, with painful ROM of the ankle and subtalar joint. There may be arthritic changes noted on x-ray to the ankle or subtalar joint.

### Diagnostic Imaging

Standard radiographs do not demonstrate a tendon tear but distinguish any adaptive changes to the subtalar or ankle joints. Standard weight-bearing dorsoplantar, oblique, and lateral x-rays should be ordered in patients displaying pain and weakness in the posterior tibial tendon. In long-standing deformities, there are arthritic changes in the subtalar and ankle joints. MRI is one of the most accurate tests that can depict the extent of pathology of the tendon (25). CT can depict the condition of the tendon; however, the definition of tendon outline is not as clear. CT scans can be helpful in identifying osseous deformities such as degenerative arthritis and subtalar joint dislocations. MRI aids the practitioner with excellent resolution of the image regarding tendon outline, synovial fluid, and vertical splits in the tendon. Axial and sagittal images demonstrate tendon pathology well (26). The axial view helps delineate tendon girth and shape, fluid accumulation, and signal changes within the tendon itself (27). Sagittal images allow the practitioner to view the extent of the pathology longitudinally. Coronal images are not as helpful in delineating posterior tibial pathology (16). Ultrasound is useful for describing the course of the tendon and can identify whether there is a tear, tendinitis, tendinosis, and peritendinitis (28,29).

In the axial view, the tendon is normally round or oval and is twice the size of the flexor digitorum longus tendon. In the normal tendon, there should be no accumulation of fluid surrounding the tendon (26). A tear on the axial image indicates mixed signal intensities, with the size of the tendon increasing or decreasing, depending on the extent of the tear.

### Treatment

Conservative treatment is reserved in those patients who are older or who lead sedentary lives. Conservative modalities include removable walking casts (Cam walkers), custom foot orthotics (to control poor biomechanics), braces, ankle-foot orthotics, orthopedic shoes with medial heel wedges, and compression stockings (16). The goal for conservative treatment is to reduce the pain and inflammation and to delay the progression of the deformity. If conservative treatment fails, surgical options should be explored. Surgery in the early phase before significant tear may include a synovectomy to the tendon sheath. After a tear, tendon transfers (flexor digitorum longus) or an isolated fusion of the subtalar joint or triple arthrodesis (fusion of subtalar and midtarsal joints) may be required.

## Achilles Tendinitis

### Anatomy

The Achilles tendon is composed of the gastrocnemius and soleus muscles (triceps surae). It forms a spiral configuration that inserts into the central one third of the posterior calcaneus. A retrocalcaneal bursa can be found between the calcaneus and Achilles tendon. The Achilles tendon is covered by a paratenon. This paratenon is a loose elastic tissue that stretches with the Achilles tendon. The central layer of the paratenon (mesotenon) is responsible for the tendon's blood supply. The action of the tendon is to decelerate and stabilize the foot, and then accelerate the foot during the gait cycle (16).

### Mechanism of Injury

Poor foot and ankle mechanics and overuse can predispose the patient to injury. A fixed forefoot equinus results in compensation at the ankle joint. The ankle compensates with dorsiflexion, allowing the forefoot and rearfoot to remain on the ground during the midstance phase of gait. This may result in an overuse injury to the tendon. Compensation at the subtalar joint for any forefoot to rearfoot imbalance places strain on the Achilles tendon. If the patient has a high forefoot varus deformity, the subtalar joint may compensate by everting the calcaneus (hyperpronation) and placing more load on the medial side of the Achilles tendon. A rigid plantar-flexed first metatarsal or cavovarus places strain on the lateral (hypersupination) side of the Achilles tendon (16).

### Physical Findings and Treatment

There are three distinct areas of pathology to the Achilles tendon: the insertion site of the tendon into the posterior one third of the calcaneus with or without bone involvement, the midportion (vulnerable zone) with peritendinitis or partial or total rupture, and the myotendinous junction (30). Most injuries are related to overuse or poor foot biomechanics. The patients will give a history of increased activity or intensity to their workouts or beginning an exercise program after a period of inactivity.

Insertional Achilles tendonitis may result from a bony abnormality to the calcaneus. Patients describe their Achilles as stiff in the morning. A bony prominence to the posterior superior lateral aspect of the calcaneus (Haglund's deformity) or insertional calcification may cause pain to the insertion site. This is quite evident in certain shoes rubbing on the area. Surgical management of this problem would be the last resort.

The patient may begin home treatment consisting of rest, ice, anti-inflammatory medication, night splints, deep transverse friction massage, and a ¼-in. heel lift to the shoes. Shoes with a lower heel counter or sneakers with a U-shaped Achilles notch to the back of the heel counter might help reduce the inflammation to the area. Stretching and strengthening exercises for the posterior leg and hamstring muscles will allow the Achilles tendon to function more efficiently. An ankle dorsiflexion stretch held for 30 seconds 10 times twice a day may help with the symptoms of pain. Home strengthening exercises using TheraBand or toe raises can be beneficial as well.

Physical therapy might be helpful in cases in which the patient is not improving on his or her own along with a removable walking cast (Cam walker). Therapy may include ultrasound, iontophoresis, deep transverse friction massage, and stretching and strengthening exercises. It is our recommendation not to inject cortisone into the Achilles tendon. The crystals of the cortisone may weaken and rupture the tendon.

Midportion pain to the tendon presents with fusiform swelling. This area is vulnerable to rupture because of the diminished blood supply. MRI is helpful in determining the extent of injury to the area. Treatment includes physical therapy (deep transverse friction massage, ultrasound, stretching exercises, and ice). Cast immobilization may be necessary in the beginning to help rest the area. We prefer removable walking casts such as a Cam walker. Home exercises for the patient should include stretching the Achilles, with ice and massage to the area.

Myotendinous junction injuries are not serious and heal readily with rest and physical therapy. In the more acute or chronic cases, a walking cast may be needed for pain relief. This type of injury heals within 4 to 6 weeks.

## Peroneal Tendinitis

### Anatomy

The peroneus brevis originates from the lateral distal two thirds of the fibula and inserts into the lateral base of the fifth metatarsal. The peroneus brevis is the strongest abductor of the foot as well as a flexor to the ankle and everter of the foot (31). The muscle stabilizes the lateral segment of the foot, specifically at the calcaneocuboid joint.

The peroneus longus muscle originates at the proximal two thirds of the lateral fibula. The tendon passes inferior to the lateral malleolus and under the cuboid and courses medially under the foot to insert into the lateral plantar base of the first metatarsal and first cuneiform. The peroneus longus is a plantar flexor and everter of the foot. The tendon at its insertion helps stabilize the first metatarsal.

### Mechanism of Injury

Injuries to the tendon may occur traumatically or insidiously from poor foot biomechanics. Forced inversion sprains may cause pain to the peroneal tendons. A patient who has a supinated foot is predisposed to this type of injury because there is increased stress to the tendons on the lateral ankle.

### Clinical Findings and Treatment

Pain to the peroneal tendons may be present inferior to the lateral malleolus, at the peroneal tubercle, or at the peroneal groove under the cuboid where the peroneus longus courses medially to insert at the lateral base of the first metatarsal and first cuneiform. Peroneus brevis tendonitis may also be present at its insertion point on the lateral base of the fifth metatarsal. Passive dorsiflexion of the first metatarsal may be helpful in determining tendonitis of the peroneus longus. Passive inversion of the calcaneus with adduction of the forefoot is a good way of testing for peroneus brevis tendinitis.

Peroneal tendinitis may occur after an inversion injury to the ankle. Patients relate pain to the ankle, with pain inferior to the lateral malleolus or at the insertion site of the peroneus brevis. There may be swelling over the course of the tendons. Athletic patients relate pain to the peroneus longus tendon with increased cutting or turning or when getting up on the ball of the foot. Pain is noted under the cuboid or on the lateral aspect of the calcaneus.

Treatment is directed at reducing the inflammation and strengthening the muscles. Rest, anti-inflammatory medication, and ice help in the acute stage of the problem. Ice pops can be made by filling a cup with water, placing a stick inside, and freezing it. Deep transverse friction massage may help break up some of the scar tissue in the area. Eversion with resistance exercises and TheraBand help strengthen the peroneal muscles.

If biomechanical abnormalities are involved, custom foot orthotics can be fabricated. Orthotics for walkers can be of three-quarter length. For the active patient, a full-length orthotic device with a long forefoot runner's post helps control the foot not only at heel strike and midstance but also at push-off. Posting of the orthotic in the rearfoot and forefoot helps keep the foot more balanced.

If the patient does not respond to conservative treatment, surgical intervention might be considered. Surgery would entail a tenosynovectomy. If the peroneal tendons are subluxing out of the groove under the lateral malleolus, the groove is usually deepened.

## Plantar Fasciitis

### Anatomy

The plantar fascia is a strong aponeurosis that originates on the medial process of the calcaneal tuberosity and fans out into a medial, central, and lateral slip. The fascia blends in with the flexor plate distally and has a connection with the plantar aspect of the toes. The central slip is the thickest, the lateral slip acts as a covering to the abductor digiti minimi muscle, and the medial slip acts as a covering to the abductor hallucis muscle (13).

The plantar fascia acts as a windlass and pulls the arch up with dorsiflexion of the metatarsophalangeal joints (32). Poor foot biomechanics can lead to increased tension on the fascia, causing inflammation and pain. This can occur with patients who have increased subtalar joint pronation, pes planus, and limited dorsiflexion. The increased pronatory forces stretch the plantar fascia and cause a pulling at the origin. This, in turn, causes pain and inflammation. Patients with a pes cavus foot type are also prone to this condition. These patients have a more rigid foot type and cannot absorb shock as well at heel strike, and that places more stress on the plantar fascia (33).

### Clinical Findings

Patients typically describe their pain after getting out of bed in the morning or after a period of inactivity. They state that the pain decreases after walking on the foot for a while (34). Most patients tolerate the condition before seeking medical help.

On clinical exam, there is tenderness on the medial plantar aspect of the heel. Some patients may have discomfort under

the midcalcaneal region of the heel. There may be tightness of the Achilles tendon insertion along with tightness to the medial slip of the plantar fascia. Poor foot biomechanics such as a pes cavus or planus deformity might be present, along with a compensated forefoot varus deformity. Upon x-ray exam, there may be a calcaneal heel spur forming parallel to the weight-bearing surface. The heel spur is not pathognomonic for this condition. The spur does not cause the pain to the heel. The heel spur is the by-product of the chronic pulling of the fascia off the calcaneus (35). Some patients might describe pain to the lateral ankle or dorsolateral aspect of the foot. This is probably related to the patient offloading the pressure to the heel and walking on the outside of the foot. This creates an overuse condition to the lateral foot and ankle structures.

Most patients respond favorably to conservative treatment. The goals of treatment are to reduce the pain and inflammation and to correct poor foot biomechanics. We prefer to treat this condition in a stepwise approach.

The first level of treatment is a simple stretching exercise for the Achilles tendon and plantar fascia. The patient stretches the Achilles tendon while still in bed with a large towel. The patient dorsiflexes the foot and holds that stretch for a minimum of 30 seconds 10 times. Stretch to the plantar fascia is done by dorsiflexing toes, holding the metatarsophalangeals, and stretching fascia in the arch region. During the day, the patient may stretch by leaning against a wall. Again, each stretch is held for a minimum of 30 seconds with the knees straight and the heels on the ground. The patient may roll the arch over a soup can or golf ball. Ice and deep transverse friction massage may also be beneficial, as may taping of the foot (35). Over-the-counter foot orthotics is also recommended. Night splints are beneficial to help keep a stretch on the posterior leg muscles and plantar fascia.

If the pain has not improved, physical therapy, cortisone injections, custom foot orthotics, and supportive shoes are discussed with the patient. Shoes should consist of adequate depth to accommodate an orthotic and should have good heel and medial countersupport. If a cortisone injection is indicated, we prefer injecting the heel with a 3-mL syringe and a 25-gauge, 1.5-in. needle. The steroid of choice is 0.5 mL of Celestone Soluspan or Depo-Medrol with 1.5 mL of 2% lidocaine (Xylocaine) plain. The practitioner should palpate for maximum tenderness and inject from a medial approach. The patient should not receive more than three steroid injections to the same area over the course of 1 year. Multiple injections to the same site can weaken the soft tissue to the area. Injections through the plantar aspect of the foot should be avoided because they are painful to the patient.

A fairly new method of treatment is extracorporeal shock wave therapy. This is a noncutting procedure performed under anesthesia (local anesthesia with intravenous sedation). It is not fully understood how this promotes healing; however, the use of electrohydraulic shock waves converts a chronic condition into an acute condition (36). Patients who do not want the traditional or endoscopic surgical procedure may consider this alternative because of the lower risks attached to the procedure.

The current standard before considering this type of procedure is 6 months of conservative care. Several studies report benefit in controlled, randomized trials without adverse effects up to 1 year following treatment (26,27).

## Hallux Abducto Valgus

### Etiology

Hallux abducto valgus occurs because of the positional and structural changes that take shape as a result of hypermobility of the first ray. It is our opinion that hallux abducto valgus is a hereditary condition caused by poor foot biomechanics. In the pronated foot, the stability of the peroneus longus is lost and the first ray becomes dorsiflexed and adducted. This creates an increase in the intermetatarsal angle between the first and second metatarsals. Finally, intrinsic instability occurs around the first metatarsophalangeal joint and the fibular sesamoid drifts laterally, creating lateral deviation of the great toe (37).

### Clinical Findings and Symptoms

Hallux abducto valgus is a progressive deformity that worsens with time. Shoes contribute to the pain but not to the deformity. The patient may have pain on the dorsomedial aspect of the first metatarsophalangeal joint. There may be erythema and a small bursa noted at the medial aspect of the joint. The patient usually has a pronated foot with decreased arch height. Patients tell the practitioner that they recently noticed their “bump” has enlarged over a short period of time. X-rays reveal an increase in the intermetatarsal angle and lateral deviation of the sesamoids, with lateral deviation of the great toe. There may not be joint pain or decreased ROM to the joint.

### Treatment

Treatment is designed to reduce the pain and to control the pronation that is causing the condition. Conservative treatment is the best initial approach. Although conservative treatment will not remove the enlarged bony prominence, the pain may decrease. Weight-bearing x-rays (anteroposterior, lateral, and medial oblique views) help the physician determine the extent of the deformity.

Ice and oral anti-inflammatory medications may help reduce inflammation. A local cortisone injection to the medial aspect of the joint may relieve pain. Over-the-counter or custom foot orthotics designed to control the biomechanical forces can help reduce pain and help realign the foot to move in a more efficient manner. If conservative therapy fails, surgical intervention is discussed. When the pain interferes with normal daily activities or if shoeing is a significant problem and conservative options have been exhausted, then surgery is considered.

There are a variety of surgical procedures, ranging from first metatarsal head and base osteotomies to fusions of the first metatarsophalangeal joint or first metatarsocuneiform joint. The goals in surgical intervention are to decrease pain, improve function, and establish a congruous joint, reduction in the intermetatarsal angle, realignment of the sesamoids, maintenance of first metatarsophalangeal joint ROM, and repositioning of the

hallux to a rectus position (37). It is preferable to place patients in custom-made foot orthotics after surgery to control the factors that led to the development of this condition.

## Hallux Limitus and Hallux Rigidus

Hallux limitus is mild to moderate decreased ROM to the first metatarsophalangeal joint. Hallux rigidus is severe limitation of motion. Either condition may or may not present problems to the patient. There have been cases (eliminate reference to personal practice) in which the patient has no motion to the joint but is pain free. The etiology of this condition may be traumatic or biomechanically induced.

### Joint Mechanics

Sixty to seventy-five degrees of first metatarsophalangeal joint dorsiflexion is necessary during the gait cycle. During the first 20 degrees, the first metatarsophalangeal joint acts as a ginglymoarthrodial joint. The motion is hingelike in nature. As the heel lifts, the ground reactive forces dorsiflex the hallux and the first metatarsal head plantar-flexes. This allows for closed-chain dorsiflexion of the first metatarsophalangeal joint beyond the 20 degrees (16).

The distal end of the first metatarsal head articulates with the sesamoid apparatus, and the base of the proximal phalanx glides along the dorsal aspect of the first metatarsal head. If the sesamoid apparatus is bound down and immobile, there is restriction of dorsiflexion to the joint. Ultimately, there is impingement to the joint causing degenerative changes resulting in arthrosis and remodeling of the joint over a period of time (37).

### Etiology

A variety of causes can contribute to limitation of motion to the first metatarsophalangeal joint. Biomechanical causes may be broken down into a long first metatarsal, long proximal phalanx, dorsiflexed metatarsal, or hypermobility of the first ray. Trauma or postsurgical bunion surgery may be another cause of this condition.

A long first metatarsal can cause jamming to the joint during the propulsive phase of gait. This causes degenerative changes to the joint. Hypermobility of the joint occurs with weakness to the peroneus longus. The peroneus longus inserts into the base of the first metatarsal and first cuneiform. Without proper first metatarsal plantar flexion, the head of the first metatarsal does not articulate with the sesamoids and the metatarsal dorsiflexes, causing limitation of motion to the joint. Congenital elevatus of the first metatarsal does not allow the first metatarsal to plantar-flex with propulsion, leading to degenerative changes (37). Acquired elevatus is seen after bunion surgery, specifically closing base wedge osteotomies of the first metatarsal. A complication to this type of bunion procedure is dorsiflexion of the first metatarsal.

Degenerative changes to the first metatarsophalangeal joint may occur with systemic illnesses such as gout, rheumatoid arthritis, psoriatic arthritis, and septic arthritis. Finally, trauma to the joint may cause degenerative changes to develop over time. An intraarticular fracture to the head of the

first metatarsal or base of the proximal phalanx may predispose the patient to early degenerative changes to the joint.

### Symptoms

Limitation of motion and pain in the first metatarsophalangeal joint occurs gradually over time. The patient complains of increased pain with increased activities. Shoes with a more flexible sole cause increased pain to the joint. Activities that load the toes and squatting become painful. Activities that require dorsiflexion of the great toe are painful, and tennis players may have significant disability.

The pain often begins over the dorsolateral aspect of the joint. There may be subtle signs of increased bony spurring at the lateral aspect of the joint on x-ray. There may be swelling to the joint and, at times, a small bursa formation over the dorsal bone spur. Lateral radiographs demonstrate a dorsal flag sign to the first metatarsal head. Eventually, x-rays demonstrate hypertrophy and squaring to the joint, with bony osteophytes (Fig. 38-5) and possible autofusion. The interphalangeal joint may develop extensus deformity and fuse.

### Treatment

The goal of conservative treatment is to reduce pain and to neutralize the deforming forces that are causing that pain. Anti-inflammatory medication and ice may give temporary

relief to early symptoms. Cortisone injections in the area of irritation may also reduce the inflammation to the joint. We prefer to mix short-acting and long-acting corticosteroids with local anesthesia into a 3-mL syringe with a 1½-in., 25-gauge needle. Not more than three injections per year are injected into the same site.

Custom-made orthotics with a Morton's extension are useful in controlling the first metatarsophalangeal joint. Morton's extension is a long post made out of rubber and is placed past the first metatarsophalangeal joint distally to the great toe. Stiffer-soled shoes and rocker-bottom soled shoes with the breakpoint of the rocker distal to the sulcus of the first proximal phalanx have also helped in reducing pain.

If conservative treatment fails, surgical intervention may be warranted. The goal of surgery is to reduce tension in the joint with mobilization of the sesamoid apparatus. This is important in procedures that are not designed to destroy the joint, such as in decompressive osteotomies of the first metatarsal.

Surgical techniques include cheilectomy, hemi-implants, total first metatarsal joint implant systems, joint destructive procedures such as Keller's bunionectomy (removing base of proximal phalanx), plantar-flexor wedge osteotomies, and arthrodesis of the first metatarsophalangeal joint. All the listed procedures have inherent risks.

**FIGURE 38-5.** Degenerative changes to the first metatarsophalangeal joint.

## FRACTURES

### Sesamoid Fractures

There are two sesamoids under the first metatarsophalangeal joint. There are tibial and fibular sesamoids. Each sesamoid bone lies within the tendon of the flexor hallucis brevis. On occasion, there may be a congenital bifurcation of these bones, and the presence of two to four sesamoid bones may be found under the first metatarsal head.

Fractures to the sesamoids can be traumatic or insidious in nature. Traumatic injuries usually are a result of forced dorsiflexion of the first metatarsophalangeal joint. Activities such as ballet dancing, high-impact aerobics, long distance running, soccer, tennis, and football lead to such injuries. The tibial sesamoid is commonly fractured more often than the fibular sesamoid because of the increased weight placed under the metatarsal head medially (16). There are times when a patient will describe pain under the foot with no direct episode of injury. Certain biomechanical conditions that cause constant stress to the sesamoid bones, such as a cavus foot, plantar-flexed first metatarsal, or peroneus longus spasm, can predispose a patient to fractures (38).

Patients typically present to the physician with pain under the first metatarsal head. There is usually swelling associated with the pain, and there may or not be a specific event triggering this pain. The patient may be seen guarding the motion to the first metatarsophalangeal joint, especially with dorsiflexion of the great toe.

X-rays such as dorsoplantar, lateral, oblique, and axial sesamoid views are typically ordered. Contralateral views should be ordered to rule out a bipartite or tripartite sesamoid. Sesamoid fractures are usually seen on x-ray as comminuted or transverse

**FIGURE 38-6.** Sesamoid fracture.

(Fig. 38-6). These fractures may be jagged and irregular with variable degrees of displacement. Congenital bipartite sesamoids appear smooth on x-ray. If there is no change on x-ray and the clinician is still suspicious of a fracture, a bone scan can be performed (39). MRI is sensitive in ruling out a fracture or other disease states of the sesamoid bone.

Treatment is directed at reducing the level of pain to the area. Rest, ice, anti-inflammatory medication, and a surgical shoe with a flat rigid sole worn for 4 to 6 weeks that prohibits push-off are initiated as conservative treatment for this condition. Once the patient is back in shoes or sneakers, custom foot

orthotics with a cutout under the first metatarsophalangeal joint is helpful in reducing the pressure under the sesamoid bones. This is particularly important in patients who have a plantar-flexed first metatarsal or cavus foot.

Sesamoid fractures are prone to delayed unions and non-unions (40). Fractures usually do not heal with bony union but rather by a fibrous bridge. Many nonunion fractures are asymptomatic (16). Those sesamoid fractures that are painful after 6 weeks may need an injection of steroid to reduce the inflammation. If pain persists and a loss of function is present, surgical excision is recommended. The clinician must be aware that if the tibial sesamoid is removed, a bunion can develop. If the fibular sesamoid is removed, a hallux varus can develop. If both sesamoids are removed, a hallux malleus can occur.

### Fifth Metatarsal Base Fractures

Two types of fractures are described at the base of the fifth metatarsal: avulsion fracture and Jones' fracture (Fig. 38-7). The base of the fifth metatarsal has a styloid process where the peroneus brevis tendon inserts. The amount of displacement and location of the fracture dictate its course of treatment.

**FIGURE 38-7.** A, B: Avulsion and Jones' fracture of the fifth metatarsal.

When there is a sudden pull on the peroneus brevis tendon, such as in a lateral inversion ankle sprain, an avulsion fracture can occur. This is a common injury in athletes when their foot lands in a supinated position. Avulsion fractures can also occur with excessive weight bearing on the lateral aspect of the foot. Patients with a supinated gait or cavus foot may be predisposed to this type of injury.

Treatment of nondisplaced avulsion fractures is usually conservative. The patient is fitted with a Cam walker or surgical shoe for 6 to 8 weeks. The patient is permitted weight bearing to tolerance. If there is significant displacement to the fracture, open reduction and internal fixation should be performed. The most popular forms of fixation are tension band and intermedullary screw fixation.

Jones' fracture is a transverse fracture in the diaphyseal region of bone 1.5 to 3 cm distal to the fifth metatarsal tuberosity. This type of fracture occurs from a vertical ground reactive force with no inversion of the foot (41). The patient pivot-shifts the foot with the ball of the foot on the ground and the rearfoot off the ground. This type of injury is less stable than the avulsion fracture because of the long lever arm of the metatarsal. The metatarsal places stress on the fracture site, making this type of fracture unstable. Healing is more difficult because of the instability and poor vascularity at the fracture site.

Treatment of choice in fractures that are moderately to severely displaced is usually open reduction and internal fixation. This is especially true for athletes and active patients. The repair is amenable to screw or plate fixation. Bone grafting is necessary, along with internal fixation, for those fractures that went on to delayed union or nonunion.

## Lesser Metatarsal Fractures

### Etiology

Metatarsal fractures are usually related to direct or indirect trauma (Fig. 38-8). The second, third, and fourth metatarsals are the most frequently fractured (16). Indirect trauma is a stress fracture caused by indirect repetitive trauma. Direct trauma is a result of a sudden impact or crush injury.

### Clinical Findings and Treatment

Clinical signs of metatarsal fractures include edema, ecchymosis, and pain over the area. It is important to evaluate the digital vascular status to ensure that there is no vascular compromise. Standard radiographs, including an anteroposterior, medial oblique, and lateral view, should be taken to assess the injury. If sagittal plane alignment is questioned, then an axial metatarsal view should also be performed. This enables one to evaluate whether the metatarsal is plantar-flexed or dorsiflexed.

Fractures to the lesser metatarsals may occur at the neck, body, or base. Metatarsal neck fractures are common because the injuring force is perpendicular to the long axis of the bone. The fracture pattern is usually oblique. If the fracture is not displaced, a short-leg non-weight-bearing cast may be used for 6 to 8 weeks. If there is displacement, then closed reduction should be attempted. Failure to realign the bone can cause

**FIGURE 38-8.** Metatarsal fracture.

shortening to the metatarsal, floating toe syndrome, or adjacent calluses under a metatarsal head (16). If closed reduction fails, the patient needs to undergo open reduction with internal fixation. Usually, intramedullary pinning with Kirschner wires (K wires) is performed.

Midshaft fractures to the lesser metatarsals have a variety of fracture patterns. These fractures are in diaphyseal bone and may be oblique, comminuted, spiral, or transverse. Nondisplaced fractures are treated with a removable walking cast such as a Cam walker for 4 to 6 weeks. If the fracture is displaced and there is significant shortening to the metatarsal, then open reduction with internal fixation may be necessary. Comminuted fractures are usually treated successfully with K wires, cerclage wiring, plates, and screws.

Metatarsal base fractures are usually transverse and are approximately 1 cm from the articular surface. An intraarticular fracture at the base is suspicious for a Lisfranc's joint injury. If there is no joint involvement, then cast immobilization is adequate.

## Phalangeal Fractures

### Etiology

Fractures of the digits are a result of sagittal, transverse, or frontal plane forces. The most common plane of injury is in

**FIGURE 38-9.** Phalangeal fracture.

the sagittal plane. Sagittal plane injuries result in compaction of the toe (object dropped on toe) or hyperextension or hyperflexion to the joints of the digit (stubbed toe). A transverse plane deformity results in an adduction-abduction injury causing a spiral oblique fracture to the proximal, middle, or distal phalanx. This is the typical “bedroom fracture,” whereby the fifth toe strikes the bedpost while walking in the dark (16) (Fig. 38-9). The frontal plane deformity is the least common injury and occurs with inversion-eversion injuries of the digit. There is a high degree of torque so that the digit is prone to neurovascular injuries along with the potential for an open wound and soft-tissue damage.

### Clinical Symptoms and Treatment

The symptoms are generally acute pain with ecchymosis and swelling to the toe. The patient has pain while wearing closed shoes. With crush injuries, there may be nail involvement causing loosening of the nail or a hematoma under the nail plate.

Radiographs are taken of any digital injury to rule out a fracture. Medial oblique, lateral, and anteroposterior views are taken. If there is displacement, then one should attempt closed reduction under local anesthesia. Closed reduction is performed by exaggerating and then reversing the injury pattern (53). Once there is satisfactory reduction, the digit is maintained in the correct alignment with tape. If closed reduction

does not adequately align the toe, then open reduction will be necessary.

Immobilization is used for stable and undisplaced fractures. It is preferable to buddy-tape the injured and adjacent digit together. The patient wears a stiff-soled surgical shoe for about 4 weeks. Ice and anti-inflammatory medication usually control symptoms.

### Orthotics

Functional orthotic devices control poor foot biomechanics. They are also beneficial in maintaining alignment after surgical intervention. A cast is made in subtalar joint neutral position while the patient is in the prone position. Two 5- by 30-in. fast-setting plaster-of-Paris splints are used for each foot. Orthotics are generally made for both feet, even if the patient has symptoms on only one.

There are a variety of lengths, materials, and posts for orthotics. The decision based on the patient’s age, activity, size, shoe style, and foot type (pronated versus supinated).

In the active patient, full-length running orthotics are designed to control the patient in heel strike, midstance, and the push-off phase of gait. If the orthotic ended just behind the metatarsal heads, there would be no control for the athlete going up on the ball of the foot. Orthotics that end behind the metatarsal heads are designed for patients who do not need control at push-off. This might be seen in a patient who needs an orthotic for daily walking.

The most common material used is the polypropylene shell orthotic. This is a firm device that has good support. Harder plastic devices are less well tolerated. Polypropylene orthotics are generally  $\frac{3}{16}$ -in. thick. On lighter patients, or when less control is needed, the device can be made  $\frac{1}{8}$ -in. thick. This gives more flexibility to the shell and fits into more shoes. Graphite is another type of material used for orthotics. This material is preferable for dress shoes because they are light and thin.

Posting to the rearfoot or forefoot is used to help balance and control forefoot and rearfoot biomechanical abnormalities such as forefoot varus, forefoot valgus, rearfoot varus, or rearfoot valgus. Posting may be intrinsic (within the shell of the orthotic) or extrinsic (outside the shell of the orthotic). When the forefoot is intrinsically posted, the distal edge of the shell is heat molded and curved to accommodate a forefoot varus or valgus deformity. Extrinsic posts are made out of acrylic or crepe and are placed under the distal medial aspect of the orthotic.

A rearfoot extrinsic post is made out of crepe or acrylic and is directly applied to the heel seat of the device. Posts are generally made to place the heel vertical to the ground or with a 4-degree varus post if the patient displays a rearfoot valgus deformity. A rearfoot intrinsic post is made within the shell of the heel. This type of post takes up less room in the shoe and is used for dress shoe orthotics.

Special accommodations can be applied to orthotics. If a patient has a repeated history of ankle sprains, a high lateral flange can be made on the lateral aspect of the orthotic. This aids in proprioception and keeps the ankle from inverting.

Decreased ROM to the first metatarsophalangeal joint is accommodated with a Morton's extension. A cutout to the shell of the first metatarsophalangeal joint can help in patients with sesamoid pain. Extra padding in the heel may help patients with plantar fascial pain.

Diabetic patients may need an orthotic to help spread their weight more evenly. If a diabetic patient has a callus under a specific metatarsal head, a device should be made with a cutout to the area to reduce stress to that part of the foot. Diabetic orthotics are generally made of Aliplast and Plastazote.

## LISFRANC'S JOINT INJURIES

The diagnosis and treatment of tarsometatarsal joint (Lisfranc's joint) injuries can be quite challenging. Appropriate knowledge of the parameters of the injury, anatomy, and consequences is paramount to successful management (42,43). Injuries of the tarsometatarsal joint are usually a result of a high-energy force. This can be broken into direct or indirect trauma. Direct injuries are usually a result of a crushing force. Indirect injuries, the most common mechanism (44,45), result from a combination of twisting and axial forces with the metatarsals plantar-flexed on the ground and the foot in a slight plantar-flexed position (46). The automobile injury is typical of this type of mechanism, with the foot being jammed against the floorboard. Quenu and Küss (47) first described this injury in 1909. They classified the injury based on metatarsal displacement into three groups (Table 38-4). In 1982, Hardcastle et al. (48) modified the Quenu and Kuss classification to include the extent and type of incongruity based on radiographs (Table 38-5).

### Clinical Findings and Treatment

The main emphasis in diagnosing these injuries should be placed on the clinical and radiographic examination along with high index of suspicion in injuries that are more occult or that may have been missed at the time of initial presentation. Physical examination reveals swelling and pain of the forefoot. An adduction or abduction deformity of the forefoot

**TABLE 38.4** Lisfranc's Dislocation Classification

Dislocation	Metatarsal Displacement
Homolateral	All displaced in same direction
Divergent	Displaced in multiple planes and differing directions
Isolated	One or more metatarsals displaced and separated

From Quenu E, Kuss G. Etude sur les luxations du metatarses du diastasis entre le 1er et le 2e metatarsien. *Rev Chir.* 1909;39:281–336, 720–791, 1093–1134.

may be present. Ecchymosis at the plantar midfoot, termed the *plantar ecchymosis sign*, may provide insight into the presence of this injury (49). Severe swelling and hematoma formation can result in a compartment syndrome, and it is of the utmost importance that the examiner assesses the patient for this condition.

X-rays are necessary for diagnosis and should be weight bearing with multiple views. Anatomically, the medial border of the second metatarsal base should align with medial border of the middle cuneiform, the space between the first and second metatarsal bases should be less than 2 mm on an anteroposterior radiograph. An oblique view should reveal alignment of the lateral border of the third metatarsal with the lateral border of the lateral cuneiform, and the medial border of the fourth metatarsal base should align with the medial border of the cuboid. Attention should be directed to the cuboid, which may also fracture and collapse on itself, resulting in a significant forefoot abduction deformity. Injuries to the metatarsophalangeal joints, interphalangeal joints, and floating metatarsals have been reported with Lisfranc's injuries (50,51). Stress views may also be required, especially in the more subtle injuries for which standard x-rays are negative but there is a high index of suspicion because of increased pain at the tarsometatarsal complex.

Pain can be elicited, with stress applied to the tarsometatarsal complex by applying an abduction-pronation stress

**TABLE 38.5** Lisfranc's Dislocation Classification

Type of Incongruity	Displacement Pattern
Type A total	Total incongruity of entire Lisfranc's complex in sagittal or transverse plane
Type B partial	
Medial	Medial displacement of first metatarsal in isolation or combination with one or more of the adjacent metatarsals
Lateral	Lateral displacement of one or more of lateral four metatarsals with first metatarsal unaffected
Type C divergent	
Partial	First metatarsal displaced medially, with one or more lateral four metatarsals displaced laterally in any number of planes
Total	First metatarsal displaced medially, with all of the lateral four metatarsals displaced laterally in any number of planes

From Hardcastle PH, Reschauer R, Kutscha-Lissberg E, et al. Injuries to the tarsometatarsal joint: incidence, classification and treatment. *J Bone Joint Surg.* 1982;64–8: 349–356.

**FIGURE 38-10.** Computerized tomography scan of a Lisfranc's injury patient with severe metatarsal segment fracture and comminution.

and an adduction-supination stress during examination. The examiner should be cautious in the acutely injured patient because this could be intensely painful. Stress radiographic examination should be performed with a local nerve block to minimize discomfort to the patient and to allow an adequate amount of stress to be applied to the joint complex. CT scans and MRI studies may also be considered, especially in instances in which there is significant osseous involvement and ligamentous injury, respectively (Fig. 38-10).

Treatment must be directed at providing ligamentous and osseous stability. This usually comes in the form of surgical stabilization. It is paramount to understand that most of these injuries require surgical intervention with fixation for 3 to 4 months followed by intense rehabilitation. Fracture reduction is essential (Fig. 38-11). K-wire fixation, previously the standard procedure, has been found to be suboptimal because of loosening and fixation failure (52). Their use should be restricted to lateral column fixation, in which some mobility of the joint complex is advantageous, or as an adjunct to other types of fixation or in which the soft-tissue envelope has been severely compromised and temporary fixation is needed until soft-tissue healing has occurred and definitive stabilization performed (53). In situations in which the patient continues to have increased pain, inability to bear weight, and swelling, improper reduction and stabilization may be the cause (53). Traditionally, postoperative patients have been maintained with no weight bearing for a period of 8 to 12 weeks in a cast. The emphasis is toward early ROM exercises in an attempt to reduce swelling and tissue fibrosis (54). Placement in a commercially removable cast after 3 weeks can provide for early ROM exercises. Progressive partial to full weight bearing is instituted. Fixation is usually removed 3 to 4 months before any unprotected weight bearing. In fact, complete ligamentous healing is believed to take 12 months and proceeds in four phases (52,55). Fabrication of orthotic devices and

**FIGURE 38-11.** Open reduction of Lisfranc's injury with an associated tarsal fracture.

modification of shoe gear depending on patient activity may be necessary.

As a result of a broad spectrum of injuries associated with midfoot sprains that range from partial sprains to complete dislocation and the controversy in treatment, Nunley and Vertullo (56) have attempted to provide a classification system to guide investigation and management. The classification scheme is based on clinical findings, weight-bearing radiographs, and bone scintigrams. It is divided into three stages (Table 38-6). Frank displacement of Lisfranc's complex was categorized by Myerson's modification of Lisfranc's injuries (45). Stage I injuries can be treated nonsurgically with cast immobilization for 6 weeks. Stage II and III injuries require surgical intervention with internal fixation following the same standards for high-velocity Lisfranc's injuries. If the patient is an athlete, sport-specific rehabilitation is necessary for overall recovery. A recent review outlines the diagnostic approach and treatment options and emphasizes the importance of urgent care to maximize a good outcome (57).

**TABLE 38.6 Midfoot Sprain Classification**

Stage I	Pain at Lisfranc's ligament complex, no displacement on weight-bearing anteroposterior x-ray plus bone scan
Stage II	First to second metatarsal bone diastasis of 1 to 5 mm on weight-bearing anteroposterior x-ray, no evidence of loss of arch height on lateral x-ray
Stage III	First to second metatarsal bone diastasis of >5 mm on weight-bearing anteroposterior x-ray, loss of arch height on lateral x-ray

## FOOT PROBLEMS ASSOCIATED WITH DIABETES

Diabetes mellitus affects about 16 million individuals in the United States (58,59). Diabetic patients account for 50% or more of the nontraumatic amputations (60–63). This high number can be explained by the fact that the number of persons with diabetes is increasing, the diabetic population is aging, and more effective coding by diagnosis enables more accurate reporting (60). Advancing age, male gender, and nonwhite racial status increase the risk for amputation (64). Pecoraro et al. (62) reported that amputations are a result of several potential pathways. These include neuropathy, minor trauma, cutaneous ulceration, infection, ischemia, altered wound healing, and gangrene. The classic triad of peripheral arterial disease (PAD), peripheral neuropathy, and infection is the harbinger of the final pathologic event of gangrene and resultant amputation (65). It has been shown that the level of amputation in diabetic patients is more distal than that of nondiabetic patients (64). Poor glycemic control, presence of retinopathy, presence of proteinuria, diabetes education, and smoking contribute to the need for amputation (66,64). The incidence of subsequent amputation either of the ipsilateral or contralateral limb rises to 50% or more at 5 years (64,67,68). The need to preserve a limb becomes even more important owing to the increased oxygen

demand and the work of walking that is required to maintain functional ambulation (69–71). The economic impact is high. The cost of diabetic ulcer care exceeds \$5 billion per year. Prevention and education are necessary if these costs are to be contained.

Deformities occurring in the diabetic patient can range from hammertoes and bunions to the devastating collapse of the foot and ankle as a result of Charcot's neuroarthropathy. This eventually leads to ulceration and a portal of entry for bacterial infection. The pathogenesis is multifaceted; however, the presence of sensory and motor neuropathy plays a significant role. Recent emphasis has been placed on collagen glycosylation resulting in decreased joint and skin mobility (72,73). Deformities associated with neuropathy and decreased joint mobility contribute to a gait pattern that produces high plantar pressure distribution resulting in ulceration. Cavanagh et al. (74) determined that foot deformities in diabetic patients with neuropathy account for increased plantar pressures and ulceration. Robertson et al. (75) have shown that there are structural differences between the forefeet of individuals with diabetes, neuropathy, and a previous ulcer and controls. They found decreased muscle density, increased metatarsophalangeal extension, and increased arthropathy. There was no difference in soft-tissue density between the groups. It is apparent that multiple risk factors can result in a cascade ultimately culminating in loss of limb (Table 38-7).

**TABLE 38.7 Risk Factors for Foot Ulceration in Diabetics**

Neuropathy	Thick mycotic nails
Sensorimotor (abnormal protective sensation)	Previous ulcers and amputation
Autonomic (dry, cracked skin)	Soft-tissue atrophy and fat pad displacement
Vascular disease	Poor hygiene
Abnormal plantar pressure (elevated in neuropathy even in the absence of deformity)	Inappropriate footwear
Abnormal gait in elderly living alone	Blind or partially sighted
Degenerative joint diseases of hip and knee	Elevated activity profile
Muscle weakness	Lack of education/low economic status
Heel cord tightness	Foot deformities
Pronation, supination deformities of the foot	Claw toes, hammer toes
Toe contractures	Hallux valgus and rigidus
	Deformities secondary to Charcot's arthropathy

Examination of the diabetic foot should include the same parameters for evaluation of the nondiabetic foot: patient history and neurologic, vascular, and musculoskeletal evaluation. Emphasis should be placed on determining the presence of neuropathy, vascular status, and the presence of biomechanical derangement. The presence of subjective complaints of numbness, tingling, or burning may be absent and may understate the presence of significant loss of sensation. Additionally, the loss of sensation may contribute to the lack of signs and symptoms that could be attributable to peripheral vascular disease. Neurologic examination should include evaluation of deep tendon reflexes, sensory testing, and motor examination. Sensory evaluation can be accomplished using the relatively inexpensive 5.07 Semmes-Weinstein monofilament. It is pressed against the skin until it buckles (Fig. 38-12). This corresponds to 10 g of linear pressure. If the patients cannot feel the monofilament at the pressure needed to cause it to buckle, they have lost protective sensation and could possibly be at risk for ulceration (76). This provides much more quantifiable information than using cotton swabs or pin prick. Loss of vibratory sensation using a 128-Hz tuning fork at the first and fifth metatarsal phalangeal joints carries the same significance as inability to feel the 5.07 monofilament (77).

Decrease or loss of pulses or signs and symptoms of ischemia, intermittent claudication, nocturnal and rest pain, shiny and cool skin, loss of hair, pallor with elevation, and rubor with dependency should be referred for vascular laboratory evaluation including segmental and digital pressures. The composition of atherosclerotic plaques in diabetic and nondiabetic patients is the same (60,65). However, PAD in diabetic patients occurs at an earlier age and progresses much more rapidly. Male and female patients are affected equally. The

**FIGURE 38-12.** Use of Semmes-Weinstein monofilament to determine the presence of protective sensation in the foot.

vessels involved in diabetic patients tend to include the tibial and peroneal arteries (66,78). Interestingly, microangiopathy, occlusive disease of the end arterial tree, does not appear to play a significant role in foot ischemia, although a thickened capillary basement membrane is present (66,78). McNeely et al. (76) have found the absence of an Achilles reflex, loss of protective sensation, and transcutaneous oxygen tension less than 30 mm Hg as independent and significant predictors of foot ulceration (76). The musculoskeletal examination should include evaluation for the presence of deformities located at the hip, knee, leg, and foot; decreased ROM; limb length discrepancies; presence of prior amputations; and gait evaluation. Abnormalities that affect the foot or superstructure, such as genu varum or valgum, hammertoes and claw toes with prominent metatarsal heads, bunion formation, limited joint mobility (especially loss of dorsiflexion owing to contracture of the Achilles tendon), equinus deformities, and prior amputations can place abnormal pressure on the foot resulting in callus production and tissue breakdown. Deformities should be accommodated in adequately fitting shoes and may require prescription for extra depth or custom-molded shoes.

Surgical intervention may be needed in select individuals to rebalance the foot to minimize pressure, especially at prominent digital and metatarsal areas and in the presence of plantar ulcers due to excessive plantar pressures from equinus deformities as a result of tendoachilles contracture. It has been shown that long-term hyperglycemia results in marked increase in tendon-fibril density secondary to nonenzymatic cross-linking of fibrillar collagen (79). Gait evaluation and inspection for abnormal shoe wear should be performed. Gait abnormalities could result in unsteady gait leading to falling and abnormal pressure on the foot and causing tissue breakdown and injury (80). Defective proprioception due to neuropathy could result in a wide gait and constant watching of the floor and landmarks resulting in frequent falls. Evaluation at each office visit should assess any significant changes and appropriate action taken to minimize potential future problems.

Charcot's neuroarthropathy results in bone destruction collapse and fracture. It is commonly mistaken for an infectious process. Diabetes is the leading cause. The incidence of unilateral involvement has been reported to be between 0.08% and 7.7%, with bilateral involvement between 5.9% and 39.3% (81). Involvement of the contralateral limb due to increased stress should remain a high concern for the clinician. Patients on the average have had diabetes for 10 to 15 years and commonly have poor diabetes control. The development of Charcot's arthropathy has been debated as a result of either a neurotraumatic origin or a neurovascular origin. It appears that a combination of factors from both theories is most likely the cause of this condition. Charcot develops as a result of autonomic neuropathy that causes an increase of blood flow to the extremities resulting in a profound osteopenia. Motor neuropathies due to imbalances create abnormal pressures. The presence of sensory loss makes the patient unaware of these pressures, and ultimate osseous destruction ensues (82,83). Armstrong and Lavery (82) have shown increased peak plantar pressures in

individuals with Charcot's arthropathy and in those who have had a neuropathic ulcer. The peak pressures were noted to be in the forefoot even in individuals with midfoot collapse, where you would expect a concentration of forces. They theorized that because they identified patients with acute Charcot's early, they eliminated the profound destruction seen at the midfoot. They further theorized that high peak pressures and neuropathy in the forefoot, coupled with an equinus deformity in the hindfoot before arthropathy develops, may predispose these individuals to the catastrophic cascade of events resulting in deformity. Armstrong et al. (84) found that performing a percutaneous lengthening of the Achilles tendon in diabetic patients at risk for ulceration due to increased peak plantar pressures resulted in decrease of these pressures. Misdiagnosis of this condition can result in significant deformity and disability.

Patients present with a red, hot, swollen foot and commonly relate the occurrence of a deformity, such as fallen arches or walking on the side of the ankles (Fig. 38-13). The clinician should always have a high index of suspicion of Charcot's arthropathy in the presence of increased skin temperature without evidence of open wounds or lymphangitis. A history of trauma may not be present. The patient may relate a strange sensation or a vague pain that is not normally present. Armstrong et al. (85) reported that 76% of patients who presented with neuroarthropathy initially presented with pain.

Radiographs initially may be normal or show osteoporosis, fracture, dislocation, or bony fragmentation. An extensive deformity may be present without fracture. This is a result of chronic ligamentous failure resulting in loss of support because of weakening of ligaments with eventual acute deformity. This

**FIGURE 38-13.** Initial presentation of Charcot's arthropathy: warm, swollen, erythematous foot without any open areas.

could be precipitated by minor trauma. If there is presence of ulceration, differentiation from an infection and osteomyelitis can prove difficult, especially if the ulcer probes to bone. It has been our experience that these patients may also have an increased erythrocyte sedimentation rate and white blood cell (WBC) count. This may require further diagnostic testing, including MRI, CT, and bone scans. The gold standard to differentiate Charcot's arthropathy from osteomyelitis is the bone biopsy, which may be required in cases in which other diagnostic evaluations have been equivocal (81). Biopsy results of a Charcot's deformity reveal synovium embedded with bone and cartilage fragments, as opposed to osteomyelitis, in which bone destruction with leukocyte infiltration would be seen.

Eichenholtz has divided the radiographic destruction into three distinct phases: development, coalescence, and reconstructive (86).

*Stage of development:* acute destructive period characterized by joint effusion, soft-tissue edema, subluxation, fragmentation of bone, intraarticular fractures, and formation of bone and cartilage debris. Continued ambulation during this stage results in significant deformity (Fig. 38-14).

*Stage of coalescence:* period of healing with decreasing edema, absorption of debris, and healing fractures (Fig. 38-15).

*Stage of reconstruction:* further repair and remodeling of bone with increased bone density and sclerosis with improved joint stability (Fig. 38-16).

Shibata et al. (87) and Sella and Barrette (88) described a stage 0, during which there are no radiographic changes but the foot is warm with swelling. Schon and Marks (89) described a stage 0 that represents an at-risk patient who is neuropathic and has sustained an acute injury. Radiographs show a simple or comminuted fracture, possibly with joint space narrowing but no fragmentation, which is associated with stage 1.

**FIGURE 38-14.** Stage I Charcot's arthropathy with x-ray evidence of fragmentation of first metatarsal and cuneiforms. Previous amputation of lateral three toes.

**FIGURE 38-15.** Stage II Charcot's arthropathy with x-ray evidence of healing fractures and sclerosis.

Sanders and Frykberg developed an anatomic pattern classification system based on distribution of bone and joint involvement (90). This recognizes five types of anatomic deformity as the end result of the Charcot's arthropathy process.

Pattern I: forefoot involvement of the interphalangeal joints, phalanges, metatarsophalangeal joints, or distal metatarsal bones; radiographic findings are typically atrophic and destructive

Pattern II: Tarsometatarsal joints (Lisfranc's joint); ulceration seen at apex of collapsed cuneiforms or cuboid

Pattern III: naviculocuneiform, talonavicular, and calcaneocuboid characterized by dislocation of the navicular or disintegration of the naviculocuneiform joint

Pattern IV: ankle and subtalar joints with severe structural and functional instability

**FIGURE 38-16.** Stage III Charcot's arthropathy with increased bone density and sclerosis.

**FIGURE 38-17.** Severe subluxation and dislocation at the ankle as a result of Charcot's.

Pattern V: calcaneal fracture; typically avulsion of the posterior tubercle

Patterns I and II are associated with bony deformity and ulceration. The most frequent patterns are I, II, and III. The most severe deformity and instability are seen in patterns II and IV. Pattern V is the least common (81). Pattern IV is the most difficult type to treat with bracing owing to severe subluxation and ulceration (Fig. 38-17). Most commonly, they require surgical stabilization in the form of fusion of the tibial-talar or tibial-calcaneal segments (Fig. 38-18).

**FIGURE 38-18.** Realignment tibial calcaneal fusion in patient from Figure 38-6.

Intervention to prevent bony breakdown and deformity requires the clinician to be astute to the harbinger of the clinical presentation of Charcot's arthropathy as mentioned previously. Strict non-weight-bearing cast immobilization is the gold standard of treatment. Prompt initiation of non-weight bearing may stop the destructive progression of this disease process, resulting in deformity. Immobilization could be obtained through total-contact casts (TCCs), standard below-knee casts, or prefabricated removable cast braces. Consideration should be given to the contralateral limb during this time of immobilization, which could be placed at increased risk for neuroarthropathy developing 4.5 months subsequently (81). This may require the use of prefabricated walking braces or orthosis to the contralateral limb. Wheelchair confinement may be necessary in situations in which both limbs are at risk (81). The non-weight-bearing status and cast immobilization should continue until all signs of inflammation resolve and serial radiographs reveal consolidation of bone. Erythema and edema will resolve first followed by warmth. Continued warmth indicates persistent inflammation that mandates continued immobilization. This process can take 2 to 6 months. Sanders and Frykberg recommend a minimum of 3 months of non-weight-bearing cast immobilization (90). After this inflammation has resolved, the Charcot's foot has entered the stage of coalescence when protected weight bearing may begin. Patellar tendon-bearing (PTB) braces, prefabricated walking braces, custom braces, and a Charcot's restraint orthotic walker (CROW) can be used. The CROW is a combination of a PTB and custom walking brace that enhances edema reduction, immobilization, and stability (Fig. 38-19). Progression to the final stage of treatment is predicated on the absence of any continued signs of inflammation, most importantly normalization of skin temperature and the presence of increased bone density and consolidation.

**FIGURE 38-19.** Bivalve ankle-foot orthosis.

The patient should maintain full weight bearing with the PTB brace, prefabricated walking brace, custom brace, or CROW for several weeks. Subsequently, a bracing prescription will depend on the deformity and may be an ankle-foot orthosis, double upright brace, or prescription footwear. Emphasis should be placed on proper footgear regardless of the magnitude of the deformity. Minimally, the patient should be placed in an extra-depth shoe with a Plastazote insole. If there is residual deformity or history of ulceration due to bony prominences, custom-molded shoes with extended steel shank and rocker bottom may be required. It should be noted that if shoe modifications are not placed properly, continued ambulation could result in development or progression of ulceration.

Surgery may be indicated for deformities associated with Charcot's arthropathy resulting in significant instability that are not controlled by bracing or shoe gear, recurrent ulcerations, and selected acute fractures (91). Interestingly, in a review of 55 patients treated with conservative care, Armstrong et al. (85) found that 25% eventually required surgical correction in the form of either exostectomies or fusion. The goal of surgery is to create a plantigrade foot that is stable, realigned, and able to accommodate shoe gear and bracing in order to prevent ulceration and limb loss. Surgical intervention may include tendoachilles lengthening, exostectomies, and realignment arthrodesis.

## DIABETIC FOOT ULCERS

Ulceration is usually the consequence of neuropathy and is compounded when deformity exists as a result of neuroarthropathy. In fact, more than 50% of patients with Charcot's deformity in a study by Pinzur et al. (92) presented with an ulcer. It is therefore important to be able to record systematically the characteristics of ulcers in order to plan treatment, monitor progress, and communicate effectively with health care providers (93). The most widely accepted diabetic ulcer classification is that developed by Meggitt (94) and Wagner (95) and is referred to as the Wagner classification. The classification is based on the depth of penetration of the wound and extent of necrosis and is divided into six wound grades (Table 38-8). The Wagner classification does not adequately address the presence of ischemia or infection. Attempts to refine the classification have resulted in several newer

**TABLE 38.8** Ulcer Classification

Grade 0	Intact skin may have bony deformity or limited skin Mobility
Grade 1	Localized superficial ulcer of the skin
Grade 2	Deep ulcer extending to tendon, bone, ligament, or joint
Grade 3	Deep ulcer with abscess or osteomyelitis
Grade 4	Forefoot gangrene
Grade 5	Gangrene of the entire foot

From Wagner FW. The dysvascular foot: a system for diagnosis and treatment. *Foot Ankle*. 1981;2:64–122.

subtypes of the original classification, specifically the Brodsky Depth-Ischemia classification (96) and the University of Texas San Antonio Diabetic Wound Classification System (93). The latter addresses the depth of the ulcer, presence of infection, and presence of clinical signs of ischemia. It uses four grades of depth (0 to 3) and four stages (A to D) based on the presence of ischemia or infection separately or in combination. The complexity of these expanded classifications makes them more difficult to implement in a clinical setting. Regardless of the classification scheme used, it is important to record the circumference, depth, and size of the wound. Description of the base of the ulcer should include the presence of granulation tissue and its consistency and color. If necrotic tissue is present, it should be described in terms of either being a thick eschar or liquefied slough. The ulcer is probed looking for sinus tracts, abscess formation, and contact with bone. It has been shown that the ability to probe to bone is highly predictive of osteomyelitis (97). Drainage is described as to its amount and odor and whether it is serous, serosanguineous, or purulent. Is the soft-tissue fluctuant with crepitus indicative of the possibility of gas in the soft tissues? Radiographs should be performed routinely to rule out gas formation, osteomyelitis, foreign bodies, and fractures. Frank bony destruction with progressive periosteal resorption and osteolysis may indicate osteomyelitis in the proper clinical circumstances. However, osteomyelitis can appear radiographically identical to diabetic neuroarthropathy (98,99). The presence of intact skin may indicate a Charcot's deformity, as described previously. If suspicion remains high for an infectious process, radionuclide imaging may be required. Technetium-99m is the most commonly ordered scan and is usually performed as a three-phase scan. Technetium localizes in areas of increased bone metabolism and vascularity, which is present in cases of osteomyelitis and neuroarthropathy. A fourth-phase scan 24 hours after injection has been used to increase specificity for osteomyelitis (98–100). Gallium-67 has been used as a scanning agent predominately because of its localization to transferrin and lactoferrin binding. Gallium also localizes to areas of increased bone activity, thereby lacking the same specificity as technetium in regard to determining an infectious process (101). WBC scans using technetium-99 HMPAO or indium-111 rely on accumulation of white cells within areas of leukocyte accumulation. Although indium is considered the most specific agent for inflammation, it is a labor-intensive procedure adding cost, and it requires a higher radiation dose. The benefit of indium is that it can be combined with a technetium bone scan to increase its specificity for detection of osteomyelitis because the energies of the two isotopes are different (98–100). The use of technetium sulfur colloid scan, which is taken up by the reticuloendothelial system, including bone marrow, has been advocated either singularly or in combination with a WBC scan. MRI appears to be gaining popularity as the modality of choice in the diagnosis of osteomyelitis; however, a rapidly progressive acute neuroarthropathy can exhibit bone marrow edema similar to osteomyelitis (98). A logical stepwise approach to identification of osteomyelitis in clinically suspect patients has been to

**FIGURE 38-20.** Superficial-appearing ulcer with sinus tract extending to dorsal aspect of foot.

order a three-phase bone scan if x-rays are negative (99,101). If the bone scan returns abnormal, proceed with a WBC scan in combination with MRI and possibly the addition of a sulfur colloid study. Proceeding initially with a WBC technetium-99 HMPAO scan may be more beneficial in the presence of osseous abnormalities on x-ray; this could be combined with a technetium sulfur colloid scan or MRI, especially for preoperative planning.

Aggressive sharp debridement of neuropathic ulcers is necessary to remove all necrotic tissue and to determine the true nature of the ulcer. What may appear to be superficial may just be the “tip of the iceberg” (65) (Fig. 38-20). The ulcer should be debrided down to healthy bleeding tissue. Clinically suspicious infected wounds should be cultured. Superficial swab cultures are unreliable owing to colonization from surface organisms. If necessary, cultures are obtained from the deeper parts of the wound after debridement (102,103). Non-limb-threatening infections may be treated on an outpatient basis empirically with cephalexin, clindamycin, amoxicillin-clavulanic acid, or levofloxacin until culture results are available and changed if necessary (101). The patient should be monitored, and if the condition deteriorates, admitted for intravenous antibiotics and possible incision and drainage procedures. Limb-threatening infections require hospitalization, intravenous antibiotic therapy, and aggressive incision and drainage. Antibiotic selection of piperacillin-tazobactam, ticarcillin-clavulanic acid, and ampicillin-sulbactam are all excellent empiric choices (101). The decision to admit the patient because of severe infection should not be based on systemic signs alone. Diabetic patients are typically immunosuppressed with defective leukocytosis and impaired intracellular killing capacity. Typically, the diabetic patient will not mount a significant leukocytosis. Gibbons and Eliopoulos (104) have shown that two thirds of diabetic patients with severe infections do not have increased temperature, chills, or leukocytosis. Uncontrolled hyperglycemia may be the only evidence of systemic disarray, which may require hospitalization for metabolic control. The presence of a deep

**FIGURE 38-21.** Total-contact cast.

abscess, especially with extension from a plantar ulcer to the dorsum resulting in cellulitis, cellulitis extending 2 cm beyond the ulcer site, and ischemia are all signs of a limb-threatening situations requiring hospitalization (102,105).

Rest, elevation, and control of edema should all be included in any treatment regimen. Removal of improperly fitting shoes and placement into a surgical shoe or other pressure-reducing footwear are required (105). Persistence by the health care community to use whirlpool treatments or advocate foot soaks as a treatment to debride tissue mechanically is detrimental and should not be part of any treatment modality. These treatments only provide for limited superficial debridement. Their prolonged use can result in maceration, progression of infection, and increased edema. Their use only delays sharp debridement and wound healing (60,65,106,107). The mainstay of treating plantar ulcers has been with the use of TCCs (spell out) (Fig. 38-21). It is believed to reduce plantar pressures at the ulcer site (108). Studies have found that ulcers healed on average 4 to 6 weeks after initiation of the TCC

(109–112). It is labor intensive, requires weekly applications, and if improperly applied can result in significant complications, including increased joint stiffness, impaired mobility, abrasions, ulceration, osteoporosis, and muscle atrophy (113,114). Unfortunately, ulcer recurrence rates can range from 20% to greater than 50% (114–117). Mueller et al. (117) performed a randomized study comparing TCC alone in 64 patients and in combination with percutaneous Achilles tendon lengthening in 31 patients. Eighty-eight percent of the TCC group and 100% of the Achilles tendon-lengthening group healed. In the first 7-months' follow-up of those patients available, 59% of the TCC group and 15% of the Achilles tendon-lengthening group had a recurrence. At the time of a 2-year follow-up, 81% of the TCC group and 31% of the Achilles tendon-lengthening group had a recurrence. This study emphasizes the importance of addressing structural imbalances associated with ulcer formation, especially the destructive nature of an equinus deformity, which has been discussed previously. If TCC is to be used, experienced individuals should apply it and the patient monitored very closely. The patient should be counseled on the modality and the importance of compliance with treatment protocols. Effective alternatives to TCC include prefabricated total-contact posterior ankle-foot orthoses, removable prefabricated walking casts, wedged or half-soled shoes, and total-contact sandals (105,109,118) (Fig. 38-22). Prolonged topical use of povidone-iodine, Dakin's solution, acetic acid, and hydrogen peroxide should be discouraged because they have been shown to disrupt the healing process. A moist environment is most conducive to wound healing. Numerous products are available, including alginates, semipermeable dressings, and collagen (119,120). Growth factors, living tissue equivalents, vacuum-assisted closure, skin grafts and flaps, electrical stimulation, hyperbaric oxygen, and ultrasound are among the available adjunctive treatment aids for wound closures and should be evaluated with regard to the individual patient's need. Wounds that have been present for prolonged periods of time with no sign of healing or improvement should be considered for biopsy. Malignancy as a primary lesion or conversion to a malignancy as seen at areas of chronic drainage from sinus tracts resulting in squamous cell carcinoma (Marjolin's ulcer) can occur and should be part of the differential in hard-to-heal wounds (Fig. 38-23). Additionally, wounds that are excised for

**FIGURE 38-22.** Total-contact sandal.

Modified from Levin ME. Pathogenesis and general management of foot lesions in the diabetic patient. In: Bowker WI, Pfeifer MA, eds. *Levin and O’Neal’s the Diabetic Foot*. 6th ed. St. Louis, MO: CV Mosby; 2001:242.

closure or debridement should be sent for histologic analysis (Table 38-9).

After an ulcer is healed, it is important to prevent its recurrence. The patient requires constant education and reinforcement. They must understand that they are constantly at risk for problems, and most will need a lifetime of care in the form of either treatment or preventive intervention. Placement of the patient into the appropriate footgear plays a pivotal role in prevention. The patient will most likely need a shoe with a pressure-relieving insole. The insoles redistribute plantar pressure over a larger surface area, thereby reducing abnormal peak pressures. Pressure areas, deformity, and type of insole determine the type of shoe. Generally, therapeutic shoes can be divided into depth shoes, which have  $\frac{3}{16}$ -in. additional depth when the insole is removed; extra-depth shoes, which provide  $\frac{1}{4}$ -in. additional depth; super-depth, which provide  $\frac{1}{2}$ -in. additional depth, and custom-molded shoes, whereby the shoe is molded to a cast of the patient’s foot (120). The extra-depth or super-depth shoe is needed to accommodate most custom-molded insoles. The shoes usually have a blucher style opening, are lightweight, and have soles that are shock absorbing. Additionally, various braces for more complicated deformities can attach to or fit into these shoes. Insoles can be modified with fillers to accommodate prior amputations. Digital amputations usually require only a spacer, whereas ray amputations and transmetatarsal amputations require a distal filler. More proximal amputations may require shortened molded shoes, rigid rocker bottoms, or high-tops with rigid counters (121,122). Various modifications to the shoe can be added to enhance ambulation and unload pressure areas. Lateral and medial heel wedges may be used to control varus and valgus deformities. Sole wedges can be added to improve gait patterns. Metatarsal bars can be placed on the outsole of the shoe to shift weight from the metatarsal heads. A rocker sole can be added to decrease pressure across the forefoot aspect of the foot. This can be incorporated with an extended steel shank, which can be used to decrease the magnitude of the toe break and facilitate roll off. When there is limited ankle motion, a solid ankle cushion heel (SACH) can be added to the heel to provide simulated plantar flexion and aid in shock absorption (121,123) (Figs. 38-24 and 38-25).

**FIGURE 38-24.** Extra-depth shoe.

**FIGURE 38-25.** Extra-depth shoe with rocker sole modification.

Proper treatment of diabetic foot ulcers begins with prevention. Patients must have a comprehensive treatment plan including adequate education. They should be trained not to self-treat and to seek professional care. Even the simple shaving of a callus must not be performed by the patient. A simple cut in an uncontrolled environment could result in loss of limb. Health care providers who have a comprehensive understanding of the pathology and feel comfortable in rendering care should provide treatment of the diabetic foot. No one person can provide all of the treatment so that it is necessary that management of the patient be undertaken in a comprehensive multidisciplinary approach. All diabetic patients should be considered at risk and their treatment tailored to fit their deformity and circumstances. The presence of the classic triad of neuropathy, peripheral vascular disease, and immunopathy must be understood in order to prevent loss of limb and provide effective treatment. It is imperative that ulcers and infections be recognized for what they are and treated aggressively but also to understand the significant ramifications of the destructive nature of neuroarthropathy. The ultimate goals should be to lower amputation rates and help maintain good function and quality of life of our patients.

# The Prevention and Treatment of Osteoporosis

Bone health is important to overall health and quality of life. Bones provide a frame that permits mobility, and protects internal organs from injury, while being a storehouse for minerals vital to the self-sustaining functions of daily life. Although osteoporosis is the most common bone disease, because there are no warning signs before fracture, it continues to be under-recognized. It is often not treated, even after osteoporosis-related fractures have occurred. Disfigurement, chronic pain, depression, disability and increased mortality can result (1). Relatively few people are diagnosed in time for effective therapy to be administered to prevent a first or a second fracture. In the United States in 2007, the national average for osteoporosis screening after hip fracture was 20% (2). This research reflects similar worldwide data (3). In a recent Canadian study, of 2,075 women age 45 or older with fracture, 81% were from a standing height (designated *fragility fracture*); however, 6 to 8 months after fracture only 21% of patients had had osteoporosis screening or treatment (4).

Compared to performance measures for other diseases, in-hospital osteoporosis management of hip fracture patients in American hospitals has lagged considerably. For instance, after myocardial infarction, doctors prescribe a recommended  $\beta$ -blocker 93% of the time prior to hospital discharge; similarly, there is 81% compliance with lipid assessment post-stroke (2). Low bone mineral density (BMD) can be considered a precipitating factor for fractures, just as uncontrolled hypertension can lead to stroke. Although advances in many areas of osteoporosis research, patient care, and health care coordination have occurred in the last 10 to 15 years, we have far to go.

As osteoporotic fractures often result from a combination of reduced quantity and quality of bone, relative neuromuscular instability, and environmental hazards, physiatrists have the expertise and opportunity to apply the multidisciplinary rehabilitation model to successfully address medical, functional and communication factors that have contributed to the development of this serious public health issue. Shinchuk et al. found that 69.8% of community dwellers (median age: 60.2) admitted to a subacute rehabilitation facility after acute hospital stay had decreased BMD (5). Because many fractures, particularly those of the hip, pelvis, and lower extremity, require in-patient rehabilitation services, physiatrists are thus in a strategic position to implement a successful osteoporosis screening cascade.

## DEFINITION

Fractures occur when applied loads are in excess of the capacity of the bone, which is dependent on the degree of bone mineralization and bone architecture. Osteoporosis is a disease characterized by low bone mass and deterioration of the micro-architecture of bone tissue, particularly trabecular bone; this leads to increased bone fragility and fracture risk (Fig. 39-1). Although bone mass is reduced in osteoporosis, the remaining bone demonstrates the normal composition of both organic (40%) and mineral components (60%).

The current procedure of greatest clinical utility for measuring bone density is the dual-energy x-ray absorptiometry or DXA. In 1994, the World Health Organization (WHO) established the term *normal bone density* to designate bone density within one standard deviation (SD) of the mean for normal young adults, and low bone density, or *osteopenia*, as the designation for those with bone density 1.0 to 2.5 SD below the mean for young adults. The number of SD from the normal young mean is designated as a T-score on the final DXA report. In the recent past, the diagnosis of osteoporosis was based solely on a bone mass measurement of 2.5 SD or more below this mean i.e., (T-score  $\leq 2.5$ ) (See Table 39-1) (6). Another means of expressing bone density is as a comparison to persons of the same age, gender, and ethnicity; this is reported as one's Z-score and is clinically most useful in following bone mass in children and adults less than 50 years old. In the last decade, however, the financial burden and impact of osteoporotic fractures on quality of life (Table 39-2) became statistically more important in treatment guidelines. As a result, in 2008, the WHO expanded the designation of osteoporosis beyond only statistical determinants to include clinical criteria: those patients with osteopenia who have had a fragility fracture, particularly of the spine or hip, are also now defined as having osteoporosis (7). When osteoporosis occurs without association with other conditions, it is defined as *primary osteoporosis*; in women, it is referred to as *postmenopausal osteoporosis*, and *senile osteoporosis* in men. Osteoporosis is also commonly seen in association with other diseases or conditions (e.g., rheumatoid arthritis, vitamin D deficiency), medications (e.g., phenytoin, corticosteroids), or disuse with immobility. These cases can be called *secondary osteoporosis*. These conditions have generalized bone mass reduction and increased risk for fracture in common (Table 39-3).

**FIGURE 39-1.** Micrographs of biopsy specimens of (A) normal bone and (B) osteoporotic bone. Adapted from Dempster DW, et al. *J Bone Miner Res.* 1986;1:15–21.

**TABLE 39.1** Defining Bone Loss by BMD

Condition	Definition
Normal	BMD is within 1 SD of a “young normal” adult (T-score $\geq -1$ )
Osteopenia	BMD is between 1 and 2.5 SDs below that of a “young normal” adult (T-score between $-1.0$ and $-2.5$ )
Osteoporosis	BMD is 2.5 SDs or more below that of a “young normal” adult (T-score $\leq -2.5$ )

Note: Definitions are based on WHO assessment of bone mass measurement at any skeletal site in white women (176).

Abbreviation: SD, standard deviation.

## EPIDEMIOLOGY

### General Population and Persons with Disability

The National Osteoporosis Foundation (NOF) estimated in 2008 that more than 12 million people in the United States would have osteoporosis by 2010, and 40 million would have low bone mass, or osteopenia (8). By the year 2020, these numbers are expected to rise to 14 and 47 million, respectively. Unchecked, these changes could double or triple the number of hip fractures in the United States by 2040 (9). *It is important to remember that persons with osteopenia far outnumber those with osteoporosis; thus, more fractures occur in the osteopenic population (3).* Fractures are also more likely to occur in trauma patients who have pre-existing low bone mass or

**TABLE 39.2** Loss of Quality of Life Years in Osteoporosis

Event	QALYs Lost Due to Event	Rationale
Hip fracture		
Acute event	0.0833	Complete loss of quality of life for 1 mo ( $= 1/12$ )
Rehabilitation or short-stay hospital (9 days)	0.0237	Complete loss of quality for 9 days ( $= 9/365$ )
Readmitted (8 days)	0.0219	Complete loss of quality for 8 days ( $= 8/365$ )
Home care services (6 mo)	0.25	Quality of life reduced by 0.5 for 6 mo ( $= 0.5 \times 6/12$ )
Nonmedical home care (6 mo)	0.25	Quality of life reduced by 0.5 for 6 mo ( $= 0.5 \times 6/12$ )
Post-hospital physician visits	0.011	Quality of life reduced by 0.5 for 8 days ( $= 0.5 \times 8/365$ )
ER, ambulance	0.0027	Complete loss of quality for 1 day ( $= 1/365$ )
Wrist fracture, acute event	0.0404	Quality reduced by 0.3 for 7 wk ( $= 0.3 \times 7/52$ )
Vertebral fracture, acute event	0.0324	33%: clinically silent with no loss of quality 57%: quality of life reduced by 0.5 for 1 mo 10%: complete loss of quality for 1 wk, and then loss of quality by 0.5 for an additional 7 wk ( $= (0.57 \times 0.5) + 0.1 \times (1 \times 1/52) + (0.5 \times 7/25)$ )

ER, emergency room.

Data from the National Osteoporosis Foundation.<sup>48</sup>

**TABLE 39.3** Classification of Osteoporosis

- A. Primary osteoporosis
  - 1. Postmenopausal osteoporosis: women
  - 2. Senile osteoporosis: elderly men
- B. Secondary osteoporosis: secondary to inherited or acquired disease states, medications or physiologic aberrations
  - 1. Rheumatoid arthritis
  - 2. End-stage renal disease
  - 3. Hyperparathyroidism; Acromegaly
  - 4. Hyperthyroidism (endogenous and iatrogenic)
  - 5. Diabetes mellitus
  - 6. Malabsorption (i.e., partial gastrectomy; gastric bypass, celiac disease)
  - 7. 25-OH and 1,25(OH)<sub>2</sub> vitamin D deficiency or toxicity
  - 8. Alcoholism
  - 9. Chronic liver disease
  - 10. Genetic factors (i.e., osteogenesis imperfecta; Ehlers-Danlos; Marfan's disease)
  - 11. Chronic obstructive pulmonary disease
  - 12. Conditions associated with medication
    - a. Glucocorticoids
    - b. Heparin
    - c. Anticonvulsants
    - d. Serotonin Reuptake Inhibitors (SSRI)
    - e. Proton Pump Inhibitors
  - 13. Conditions associated with hypoestrogen state
    - a. Anorexia; bulimia
    - b. Exercised-induced amenorrhea (i.e., FAT)
  - 14. Conditions associated with disuse
    - a. Tetraplegia/paraplegia/hemiplegia
    - b. Immobilization
    - c. Prolonged bed rest
  - 15. Malnutrition
  - 16. Chronic liver disease
  - 17. Idiopathic hypercalciuria
  - 18. Low Testosterone, or Androgen insensitivity (Klinefelter's and Turner's syndromes)
  - 19. Systemic mastocytosis
  - 20. Adult hypophosphatasia
  - 21. Malignancy (multiple myeloma, leukemia, lymphoma)

osteoporosis (10). Of the 10 million people in the United States estimated to have osteoporosis, women account for 8 million of those affected, and men for 2 million; another 12 million men are estimated to be at risk for the disease (11). When compared with other ethnic/racial groups, risk is increasing most rapidly among Hispanic women (12).

In the more generalized population, more than 2.0 million fractures per year in the United States in 2005 were directly related to osteoporosis. Of those, approximately 25% were at the hip and pelvis (13) and 30% at the spine (11). One-half of American women and up to 25% of men will have an osteoporotic fracture in their lifetime. The prevalence of osteoporosis at the hip is 17% for white, 14% for Hispanic, and 6% for black postmenopausal women (14). As life expectancy increases,

osteoporosis will become more prevalent in men and women. Its importance as a public health problem is underscored by the fact that the lifetime risk of hip fracture in women is larger than the sum of lifetime risks of having breast, endometrial, and ovarian cancer. At present, hip fractures constitute on average 77% of the cost burden of fragility fractures in the United States (15).

Because of lower bone mass accrual in youth, and higher rate of bone loss in mid- and late life, women are more susceptible than men to osteoporosis (16). In the past, osteoporosis has been largely neglected in men, but research shows it is an important clinical and public health problem. Based on current WHO diagnostic criteria for osteoporosis, its prevalence is 4%, 2%, and 3% among white, Mexican-American, and black men age 50 and older, respectively (17). It is now recognized that the prevalence of hip fracture in men is approximately one-third to one-half that of women of similar age. Mortality after fracture in men, however, is consistently higher than that in women (18). Although hip fracture rate in women is two to three times that of men, 1-year mortality after hip fracture for men is nearly twice that of women (19). Although women lose bone mass rapidly during menopause, by age 70, calcium absorption has decreased in both sexes, resulting in an equal rate of bone loss by age 65 in men and women. After the age of 75 years, osteoporosis affects half the population, men and women equally.

The epidemiology of the Women's Health Initiative identified clinical risk factors and biomarkers for 5-year hip fracture risk in postmenopausal females, and enhanced our knowledge of race and ethnic differences in this population (20). The prevalence of osteoporosis in white women is similar to that of Hispanic and Asian women. However after age 50, 20% of white and Asian women and 7% of men are diagnosed with osteoporosis compared to only 5% of non-Hispanic black females, and 4% of males (14). While African-Americans are less likely to have osteoporosis, once diagnosed, they have the same increased risk of fracture (14). After hip fracture, black women have a higher mortality than white women, thought to be due to in part to more advanced age and differences in medical care (19).

Osteoporosis occurs commonly in the rehabilitation patient population in both its primary and secondary forms. In Greek patients 1-year post-stroke, Lazoura et al. demonstrated that bone loss at the paretic hip relative to the nonparetic hip in males (11.8% at the femoral neck, and 10.4% at the greater trochanter) was less than perimenopausal women of the same age (13% and 12.6%, respectively). However, contrary to U.S. trends, there was no statistical difference between male and female in prevalence of osteopenia (53.3% and 52.2%, respectively), but males were more likely to have osteoporosis (20% vs. 13%) (21).

Smeltzer et al. demonstrated that community-dwelling American women with disabilities (control group) had a higher incidence of osteoporosis (22.6% vs. 7%) and low BMD (53.1% vs. 40%) than nondisabled postmenopausal women; only 50.9% of the controls were postmenopausal, with mean age of 50.6 (22). This corroborates findings by Nosek et al.

that women with disabilities develop osteoporosis earlier (23). In Smeltzer's DXA screening of subjects, the highest incidence of osteoporosis was seen in women with spina bifida (69.2%), spinal cord injury (65%), post-poliomyelitis (44.2%), and cerebral palsy (40%). Risk factors included Caucasian race (87.6%), lack of exercise (64.6%), menopausal status (50.9%), and medication-associated risk (44.8%). Estrogen replacement therapy was the most common prescribed treatment (19.7%), with alendronate prescribed for 5.6%. Only one-quarter of these women with disabilities had been previously screened for BMD, and only one third were taking calcium supplementation (22).

Secondary osteoporosis is not restricted to disabled adults; children with disabilities, including cerebral palsy and juvenile idiopathic arthritis, are also susceptible (24,25). Although screening and treatment protocols are not as well studied as in adults, these children are also at increased risk for low bone mass, osteoporosis, and fractures compared to their peers (26–29). Pediatric patients with cerebral palsy are particularly susceptible to spontaneous fractures (30).

Loss of bone mass with immobilization is most dramatically demonstrated in spinal cord injury patients, in whom sublesional bone mineral loss occurs in the lower limbs and pelvis; in paraplegic patients, and also in the upper limbs in tetraplegic patients. Dauty et al. showed in 2000 that sublesional BMD in spinal cord injury patients decreased 41% relative to controls at 1-year post-injury. It is most prominent at the tibia (–70%) and distal femur (–52%), the most common fracture sites (31). The spine bone mass does not significantly decrease (32).

The morbidity associated with osteoporotic fractures is high (33). In 1995, there were greater than one-half million hospitalizations, and 800,000 emergency room encounters secondary to osteoporotic fractures. Of these, hip fractures are the most devastating (34). Hip fractures account for nearly 50% of all osteoporotic fracture hospitalizations in the United States, compared to 8% for vertebral fractures (35). *In terms of resulting disability, WHO data show that, post-fracture, one hip fracture is the equivalent to four vertebral fractures, or twenty fractures at other sites (3).* The direct cost of osteoporosis is estimated at \$12.2 to 17.9 billion annually in the United States. Because of increased life expectancy, the number of hip fractures could increase three- to eightfold by 2040 (9). Therefore, early screening and implementation of exercise, diet, fall prevention, and pharmaceutical strategies will become even more crucial.

Most of the social and economic burden of osteoporosis relates directly to hip fracture as well (15). Although some fracture patients suffer only temporary disability, many patients face deformity, loss of function, dependence, or institutionalization. Hip fracture almost invariably results in hospitalization and is a strong risk factor for acute complications (36). Fewer than 50% of hospitalized patients with hip fracture recover their prefracture competence in activities of daily living (ADLs); 80% are unable to perform at least one instrumental ADL, such as shopping or driving (37) and only 25% regain previous levels of social functioning (38). Nine of every 100

elderly, white female hip fracture patients will die because of that fracture within 5 years (39). Of those who are ambulatory before hip fracture, studies have shown that 20% require long-term care afterward (11). Hip fractures are now clearly associated with increased mortality as well; approximately 20% of these patients will die within 1 year of their fracture (40).

Although less debilitating than hip fractures, fractures at the spine, wrist, and other sites are more common, and result in considerably more morbidity than hip fractures. Fractures of the vertebra are the most common, more than 700,000 per year in the United States (11), and are largely responsible for the “dowager’s hump” deformity. These fractures, when severe, may cause chronic back pain, loss of height, and disability (41), as well as balance dysfunction, and altered abdominal anatomy, leading to abdominal distention, constipation, pain, and reduced appetite. Multiple thoracic fractures can lead to restrictive lung disease as well (42–44). Because of adverse changes in the ability to perform ADLs, the resulting impairment may be equal to that seen after hip fracture (45). Wrist fractures more likely to result in short-term disability, such as pain, loss of function, nerve entrapment (particularly carpal tunnel syndrome), bone deformity, and arthritis. Past studies have demonstrated a 30% risk of complex regional pain syndrome with wrist fractures (46,47).

The WHO has established a quantitative value to the impact of osteoporotic fractures by determining the quality-adjusted life year (QALY) associated with these fractures, with perfect health for 1 year assigned a QALY of 1, and death assigned a QALY of 0. With this measure, a disability that reduces a person’s self-assessed quality of life by half, compared with perfect health, is assigned a QALY of 0.5. A focus group of postmenopausal women generally agreed with determinations made by the NOF Committee from the WHO QALY model. Similarly, the effectiveness of various pharmacologic treatments in preventing fractures and their consequences was based on available evidence from randomized controlled trials. Although effectiveness of rehabilitation strategies was not reviewed, the assumptions of effectiveness coupled with costs enable the calculation of the expected cost per QALY for any interventional strategy. With this methodology, a statistician can determine the likelihood of a particular strategy providing a favorable cost:benefit ratio for the health care system. Table 39-2 provides examples of QALYs assigned to various outcomes after NOF analysis (48).

## ETIOLOGY AND RISK FACTORS

Fracture risk is dependent on the specifics of an individual’s genetic profile, peak bone mass, and strength of bone achieved in one’s lifetime and the subsequent rate of bone loss. There are identified risk factors and causes of low bone mass and osteoporosis that contribute to this fracture risk model. In primary osteoporosis, multiple etiologic factors may act independently or in combination in an individual patient to produce diminished bone mass. In secondary osteoporosis, specific

causes are identified. The presence of one or more of these factors in the elderly increases the risk of accelerated bone loss and subsequent fracture. The “weighting” of each of these risk factors in terms of relative importance as an etiologic factor is not always well defined, although estrogen depletion; calcium, vitamin D, and testosterone deficiency; smoking; advanced age; positive family history; diminished peak bone mass; diminished physical activity; and history of previous fractures are important. Corticosteroid use of 5 mg/day for a minimum of 3 months is also an important risk factor, as are such factors as excessive alcohol intake, cigarette smoking, use of antiseizure medication, and excessive thyroxine replacement and falls (Table 39-4).

Glucocorticoids reduce bone mass directly by inhibiting bone formation and indirectly by inhibiting the secretion of androgen in the pituitary-gonadal and adrenal systems. Secondary hyperparathyroidism then results from the induced limitation of calcium absorption by the intestine, and calcium reabsorption in the renal tubules. Although vertebral fractures are commonly associated with chronic glucocorticoid use, atraumatic fractures of the ribs and metatarsals can also be found (49).

In senile osteoporosis in men, alcoholism, tobacco abuse, and low testosterone are significant risk factors. Unfortunately, the specific mechanism of progression for osteopenia and osteoporosis in men is difficult to delineate (50). There is early research evidence that smoking cessation increases BMD at the hip; this is significant, as smoking can increase the risk of hip fracture in men and women by up to 30% (51). Of the 30% to 50% of patients requiring chronic glucocorticoids who fracture, the elderly and postmenopausal females are at highest risk.

**TABLE 39.4 Risk Factors for Osteoporotic Fractures**

Personal history of low-impact fracture
Current low BMD
Hip fracture of either parent
Caucasian race
Advanced age
Female sex
Dementia
Recurrent falls
Inadequate physical activity
Poor health/frailty
Current smoker
Low body weight
Estrogen deficiency
Corticosteroid use
Testosterone deficiency
Vitamin D deficiency
Low lifetime calcium intake
Alcoholism
Impaired eyesight despite correction

Risk factors in persons with disability can differ from the general population. For instance, reduced mobility, vitamin D deficiency, progressive time from onset of disability, and gender in stroke patients have been documented (52). Although the prevalence of osteoporosis in the traumatic brain injury population is not well studied, high risk for hypogonadism and immobility in this population is likely to predispose them to low bone mass (53). Time after onset of spinal cord injury, and associated decrease in mobility, also correlates with increased risk in the lower limbs for low bone mass and fractures (32).

## **PATHOGENESIS**

Osteoporosis is a heterogeneous disease with multiple causes. Although the pathogenesis of bone mass loss in secondary osteoporosis may be readily apparent (e.g., corticosteroid excess, or the lack of muscle effect on bone with subsequent negative bone remodeling in paraplegia), the exact pathogenesis of primary osteoporosis may be more difficult to define. Low bone mass may be attributable to failure to achieve adequate bone mass at skeletal maturity (age 13 to 25 for women) and/or subsequent age-related and postmenopausal bone loss. Although low bone mass is principally associated with fracture, other determinants of fracture include the quality of the bone (e.g., trabecular architecture), the ability to heal trabecular microfractures, and the propensity to fall (54,55). The pathogenetic basis of inadequate bone mass, particularly in the elderly, also may be considered from the standpoint of tissue, cellular, and hormonal abnormalities.

## **Tissue Abnormalities**

Although cellular and hormonal abnormalities undoubtedly contribute to osteopenia and osteoporosis, the basic abnormality in all types of osteoporosis is a disturbance of the normal bone-remodeling sequence at the tissue level. Therefore, to fully understand the pathogenesis of osteoporosis, knowledge of bone remodeling is necessary.

Bone is constantly turning over (remodeling). The skeleton is a reservoir for 99% of the body's calcium; remodeling provides calcium to the organism without sacrificing the skeleton. In addition, remodeling allows bone mass to respond to increased and decreased muscle activity (e.g., bone mass is increased in a tennis player's dominant arm). The initial event in bone remodeling with normal bone turnover is an increase in bone resorption, as mediated by the osteoclast (the cells responsible for bone resorption). This event is typically followed within 40 to 60 days with an increase in bone formation, as mediated by the osteoblast (the cells responsible for bone formation). Bone resorption and formation are normally “coupled”: an increase or a decrease in resorption produces a corresponding increase or decrease in formation, so that the net change in bone mass is zero. In postmenopausal osteoporosis, and possibly in senile osteoporosis as well, bone resorption is increased without a corresponding increase in bone formation, thereby leading to a net loss in bone mass. In this case, bone remodeling is described

as “negatively uncoupled.” In other forms of osteoporosis, particularly those associated with corticosteroid-induced osteoporosis, a primary decrease in bone formation may occur. The end result is the same—a net loss of bone mass, with concomitant increasing risk for fracture as bone density decreases. Abnormalities of bone remodeling at the tissue level will therefore contribute to the pathogenesis of osteoporosis.

### Cellular Abnormalities

Conclusive evidence of cellular abnormalities contributing to the pathogenesis of primary osteoporosis is building. In its simplest terms, the rate of growth and activity of osteoblasts falls behind that of osteoclasts, resulting in a loss of bone density. These processes may be separate from abnormalities of bone cells that occur with aging alone. For instance, it may be a failure of the osteoblast, as a result of either decreased cell number, or decreased cell activity, which accompanies advancing age, but is not specific for osteoporosis. Recent investigations of the communication system between osteoblasts and osteoclasts hold promise, particularly the osteoblast CFU-M and RANKL proteins, which stimulate osteoclast activity (Fig. 39-2A), and its protein osteoprotegerin (OPG), which binds RANKL and inhibits osteoclast activity (Fig. 39-2B). The balance between RANKL and OPG production may determine

the rate of bone resorption (56). In 2001, a study by Gong et al. associated patients with a dysfunctional receptor (lipoprotein receptor–related protein-5) with severe osteoporosis and pseudoglioma (57); overactivity in this receptor has been shown to form strong bones.

### Hormonal Abnormalities

Many hormonal agents may affect bone cell function and bone mass. Although there are numerous age- and menopause-related alterations in the physiology of these hormones, a specific pathogenetic hormonal abnormality in osteoporosis (excluding the osteopenia associated with hypercorticism and hyperparathyroidism) has not been conclusively defined. Estrogen deficiency remains the most frequently incriminated factor in the pathogenesis of postmenopausal osteoporosis in women, while testosterone deficiency is considered a potential cause in younger men.

Indeed, estrogen deficiency of any etiology, including menopause, early oophorectomy (58), and functional hypogonadism associated with chronic strenuous exercise (female athlete triad [FAT]) (59), should be considered a prime risk factor for bone mass loss. Estrogen deficiency from any cause results in increased skeletal responsiveness to parathyroid hormone (PTH) and increased bone resorption, a transient increase in the

**FIGURE 39-2.** Osteoporosis is caused by disruption of normal bone remodeling sequences. **(A)** Role of RANK and RANKL in bone remodeling. **(B)** Regulation of RANK/RANKL binding by osteoprotegerin (OPG). (Delmas PD. *J Clin Densitom.* 2008;11:325–338, Fig. 39-4A. Adapted with permission from Boyle WJ, et al. Osteoclast differentiation and activation. *Nature.* 2003;423:337–342).

serum calcium level, and a resultant decrease in PTH secretion. With such a decrease, reduced production of the active form of vitamin D,  $1,25(\text{OH})_2$  cholecalciferol would be expected, with a consequent decrease in calcium absorption. A number of these hormonal perturbations are demonstrated in osteoporotic populations; estrogen deficiency alone, however, is an incomplete pathogenetic explanation for osteoporosis because all postmenopausal women are relatively estrogen deficient, but not all develop osteoporosis. The serum level of immunoreactive PTH increases with aging (60) and is increased in about 10% of postmenopausal osteoporotic women. In these women, the increase in PTH may be related causally to bone loss. In most postmenopausal osteoporotic women, however, PTH levels are normal or low compared with those of normal elderly women via the mechanisms noted previously, and in these patients the pathogenetic contribution to osteoporosis is less clear. The situation is complicated by the common finding of vitamin D inadequacy, which may also lead to mild elevations of PTH. Suffice it to say, in all postmenopausal women, bone resorption increases more than bone formation, leading to significant bone loss in some women.

A number of vitamin D abnormalities occur with aging, although an abnormality specific for osteoporosis (rather than simply aging) has not been defined. Decreased levels of  $1,25(\text{OH})_2$  are noted with increasing age. A postulated defect in the osteoporotic elderly person of the renal  $25(\text{OH})$  vitamin D  $1\text{-}\alpha$ -hydroxylase enzyme in response to PTH has not been conclusively proven (61,62). Older people may simply not be able to make vitamin D in response to sunlight, compared to younger people. Nevertheless, calcium absorption does decrease with advancing age, is lower in postmenopausal osteoporotic women, and its decline is associated with increased risk for hip fracture.

There is a great deal still unknown about the pathogenesis of osteoporosis. Other hormones that may play a role in skeletal loss with aging include testosterone, insulin-like growth factor-I (IGF-I), and dehydroepiandrosterone sulfate (DHEAS). A deficiency of the hormone calcitonin also could contribute to on-going bone loss, although it is unlikely that it exerts a major pathogenetic effect in osteoporosis. Calcitonin inhibits the production and activity of osteoclasts, and thus decreases osteoclastic bone resorption. Serum levels of immunoreactive calcitonin decrease with age and are indeed lower in women than in men. In addition, decreased calcitonin secretion in response to calcium stimulation has been noted in some, but not all, osteoporotic populations (63,64).

In a study of the spinal cord-injured population, Szollar et al. found that serum levels of calcium and calcitonin could not be correlated with changes in bone mass. However, in this study of patients with spinal cord injuries, the PTH level decreased in the first year after injury and started to increase 1 to 9 years after injury. Osteoblast activity decreased immediately after injury in these patients, with consequent dramatic decreases in bone degradation. In fact, loss of BMD in the proximal femur was measurable at 12 months following injury in all 176 persons with paraplegia or tetraplegia. Of significance, risk for fracture increased between years 1 and 9 after injury in the 20- to 39-year age group, but continued

increasing to year 19 after injury in the 40- to 59-year age group before plateau. This study also showed that BMD in the spine actually increased from weight bearing 1 to 9 years after injury in all study participants, though becoming significant only in those with paraplegia in the 20- to 39-year age group 10 to 19 years after injury (32).

Fractures occur in this population most frequently in the pelvis and lower extremities, particularly the tibia, and correlated with sites of most bone density loss. Similar to the general population, women with spinal cord injury tend to develop osteoporosis more frequently than men with spinal cord injury. Research is needed comparing risk of osteoporosis in patients with spinal cord injury of different races.

### Genetic Abnormalities

The degree of peak bone mass achieved and the amount of bone loss as we age determine our risk of osteoporosis. Complex genetic and environmental factors determine these contributing factors. It is likely that a cohort of genes contribute to a predisposition to osteoporosis and that they differ among different ethnic backgrounds (65). Definitive identification of all candidate genes is not established, but numerous gene susceptibilities are implicated, including abnormalities in receptors for the active form of vitamin D<sub>3</sub> (calcitriol), estradiol, and PTH as well as genes coding for TGF- $\beta$  and IL-6. These genes are associated with achieving peak bone mass and bone remodeling processes, and are active throughout the lifespan (66).

### Spinal Cord Injury

Although disuse is thought to play a role in the development of osteoporosis in this population, neural factors are also implicated, as is an impaired PTH—vitamin D axis and calcium/phosphate metabolism (67). There is no demineralization in supraspinal areas following injury, and weightbearing in the spine is thought to limit loss of bone mass in vertebrae. It is likely that some of this increased spine bone density was due to development of osteophytes is suspected as all patients age. Spasticity, degree of injury, female sex, age, and duration after injury negatively influence bone mass. Reduced intestinal absorption and increased renal elimination of calcium, inhibition of sex steroids, pituitary suppression of Thyroid Stimulating Hormone (TSH), and insulin resistance and IGFs may also contribute (68), but the majority of patients with spinal cord injury have decreased bone mass below the lesion. Animal models have demonstrated increased osteoclast activity, with severe bone loss (48% trabecular and 35% cortical), decreased mineral apposition, and growth plate abnormalities consistent with osteoblast dysfunction (69), and elevated RANKL mRNA induction (70).

In his study of the spinal cord-injured population, Szollar et al. found that serum levels of calcium and calcitonin could not be correlated with changes in bone mass. However, in this study the PTH level decreased in the first year after injury and started to increase 1 to 9 years after injury. Osteoblast activity decreased immediately after injury in these patients, with consequent dramatic increases in bone degradation. In fact, loss of BMD in the proximal femur was measurable at 12 months following injury

in all 176 persons with paraplegia or tetraplegia. Of significance, risk for fracture increased between years 1 and 9 after injury in the 20- to 39-year age group, but continued increasing to year 19 after injury in the 40- to 59-year age group before plateau. This study also showed that BMD in the spine actually increased from weight bearing 1 to 9 years after injury in all study participants, though becoming significant only in those with paraplegia in the 20- to 39-year age group 10 to 19 years after injury (32).

Fractures occur in this population most frequently in the pelvis and lower extremities, particularly the tibia, and correlated with sites of most bone density loss. Similar to the general population, women with spinal cord injury tend to develop osteoporosis more frequently than men with spinal cord injury. Research is needed comparing risk of osteoporosis in patients with spinal cord injury of different races.

## CLINICAL EVALUATION FOR OSTEOPOROSIS

Although the first clinical indication of osteoporosis, either primary or secondary, is usually a fracture, it is optimal to screen and treat patients, both male and female, prior to first fracture.

### Quantitating Bone Mass

A number of clinical parameters positively correlate with bone mass, such as paraspinal muscle strength in postmenopausal women and grip strength in premenopausal women and men. Although these are useful methods, they do not substitute for precise quantitation (71). Plain radiographs of the spine are relatively insensitive in quantitating bone mass because 30% to 35% of bone mass must be lost before demineralization is detected. They are, however, sensitive and reliable to assess for fractures of the spine when unexpected height loss is noted, or when fractures are suspected in axial or peripheral bone.

Several noninvasive procedures have been developed over the past 50 years to quantitate bone mass (bone density). The current procedure of greatest clinical utility, DXA is noninvasive, quantifies primarily trabecular (cancellous) bone at the spine and hip with an acceptable precision and accuracy, is reasonably simple to perform at a reasonable cost, and is associated with low radiation exposure. Most importantly, it predicts which patients are at risk for subsequent fracture and can be repeated to assess therapeutic response to treatment. The DXA technique also satisfies requirements for ionizing radiation safety to the greatest degree, as bone density measurements can be obtained within 30 seconds to 2 minutes with a radiation exposure of approximately 10 mrad—one-sixth the exposure of a chest x-ray—with 99% precision and approximately 97% accuracy. CT measurements of the spine provide an exclusive assessment of trabecular bone, and actual volumetric density, but the technique is compromised by high radiation exposure and lower precision.

WHO recommendations for baseline and follow-up testing are based on DXA measurements at axial sites (spine and hip). For patients in whom the spine cannot be measured, the forearm is substituted. The spine and the distal forearm contain primarily trabecular bone, metabolically more active than cortical bone, and preferentially altered in osteoporosis, thus most

affected by medications used in the treatment of osteoporosis. The hip and parts of the forearm also have cortical bone. The vertebrae and hips are also the fracture sites likely to cause the most disability. WHO guidelines are adapted to the epidemiology of individual countries and are well described in special position papers by the NOF Guide Committee (72,73). As WHO DXA standards were established from research of white, postmenopausal women, some controversy exists in interpretation of DXA for men, premenopausal females, nonwhite populations and children. The International Society for Clinical Densitometry (ISCD), for example, recommends use of a single normative database for all women, and the use of a male normative database to calculate T-scores for men (74,75). There is increasing consideration being given to the use of Z-score values for assessing bone health in children, as is done in Canada (76). Although peripheral measurements with other techniques such as pDXA, pQCT, and ultrasound may predict hip and spine fracture similar to DXA, they have less clinical utility than axial measurements. Because of low cost, portability, and lack of radiation exposure, peripheral measurements with ultrasound have evolved primarily as a screening tool, which, when positive, instigates further clinical evaluation and DXA screening (77).

Revised 2008 WHO guidelines for DXA screening and treatment shifted from a T-score-only basis for treatment to evidence-based assessment of the 10-year risk for fracture at hip and other sites, based on age, gender, race, bone density values and known osteoporosis and fracture risks. Guidelines were then adapted to demographic and health care profiles of individual countries (72,73). Interpretation of these guidelines, though, can vary among diverse governmental and medical specialty organizations. All women 65 or older (men perhaps at age 70), and patients with known fragility fractures after age 45, particularly at the hip or spine, should be screened for osteoporosis via DXA. Screening should also be considered for younger adult women and men with at least two known risks, such as early menopause, tobacco abuse, corticosteroid dependence, or testosterone-blocking agents (see Fig. 39-3, Algorithm for Osteoporosis Management). Protocols for DXA and laboratory screening in children and young adults with chronic disability (i.e., cerebral palsy or spinal cord injury), and with medical conditions associated with osteoporosis such as eating disorders and FAT, are not well established, but the ISCD has published recommendations ([www.iscd.org/Visitors/positions/OP-Index.cfm](http://www.iscd.org/Visitors/positions/OP-Index.cfm)) (74). Fragility fractures in these populations warrant at least baseline DXA assessment. Screening, interpretation of results, and treatment for loss of bone density must be individualized until more research can be done in these populations.

The FRAX WHO Fracture Risk Assessment Tool (Fig. 39-4), developed at the University of Sheffield, in England by Kanis et al. assists the clinician in treatment guidelines for patients with low BMD (osteopenia, DXA T-score between -1.0 and -2.5) without previous pharmaceutical intervention (78). After inserting data reflecting patients' gender, age, race, body weight, and height, known osteoporosis risk factors, and femoral neck bone density (in gm/cm<sup>2</sup>) with the manufacturer of DXA equipment, the FRAX tool establishes a treatment threshold in accordance with WHO guidelines. In the United States, if the

data indicate a 10-year fracture risk at the hip of greater than or equal to 3%, or at other major sites of greater than or equal to 20%, prescription medications should be considered in these populations (79). If the patient is not started on pharmacologic therapy, subsequent screening by FRAX or with DXA is recommended at 2 years, although some low-risk patients can be assessed at much longer intervals. For those patients who are at risk for fracture and begin therapy, a follow-up DXA is suggested at 2 years, to assess response to treatment. If femoral neck BMD is not available (e.g., in a patient with bilateral hip surgery), FRAX tool must determine fracture risk by body mass index (BMI).

### Bone Markers

Serum and urine markers of bone resorption and formation are diagnostic modalities used primarily to monitor efficacy of prescription therapy. In this sense, the markers may be complementary to bone density assessment. Current rate of bone resorption is most commonly assessed with a urinary marker n-telopeptide of type I collagen (NTX), and c-telopeptides of type I collagen (CTX) (80). The n-telopeptide (NTX) measurement results from 24-hour urine calcium collection, normalized for creatinine; urine is collected within 48 hours of routine serum osteoporosis laboratory studies to best define calcium metabolism pathway abnormalities (as are seen in Table 39-5, Laboratory Tests in Disorders of Calcium Metabolism). However, for convenience, a second-void fasting spot urine NTX can be preferred, due to calcium intake variance during a 24-hour period. Serum levels of NTX and CTX can also be tested. It should be noted, however, that all bone turnover markers have considerable day-to-day variability. Thus, many experts use them in only specific cases when knowing the rate of bone turnover is necessary.

### Clinical Evaluation of the Patient at Risk for Osteoporosis

Patients at risk for osteoporosis require careful evaluation, consisting of the following elements. A thorough history is required to determine the presence of risk factors for osteoporosis such as menopausal status, family history of hip fracture, and certain medications (Table 39-6), and to exclude medical conditions leading to secondary osteoporoses (see Table 39-3). A separate intake questionnaire for osteoporosis to expand standard intake

**TABLE 39.6** Etiologic Factors Contributing to the Risk of Osteopenia/Osteoporosis

1. Estrogen depletion
  - a. Postmenopausal state (natural or artificial)
  - b. Exercise-induced amenorrhea, anorexia nervosa
2. Calcium deficiency
  - a. Inadequate calcium intake
  - b. Malabsorption
  - c. Lactose intolerance
3. Diminished peak bone mass at skeletal maturity; varies with sex (women > men), race (whites > blacks), and heredity
4. Diminished physical activity
5. Testosterone depletion
6. Aging
7. Low body weight (adipose tissue is the major source of extragonadal estrogen production postmenopause)
8. Alcoholism; smoking
9. Excessive coffee intake (>4–6 cups daily); excessive dietary protein or salt intake (increased calcium loss in the urine)
10. Medications: corticosteroids, thyroid hormone, phenytoin

Data from the National Osteoporosis Foundation, Prevention, NOF.org.

history intake can be helpful. History of previous fragility fractures and sites of persistent pain (i.e., atraumatic vertebral compression fracture) must be identified. Identify any history of falls or associated risk factors such as poor vision, bladder urgency, or peripheral neuropathy (Table 39-7). Document any loss of height from early adulthood (average loss of 2 to 3 inches from occiput to sacrum is expected between the ages of 40 and 80 (49)), and include in DXA prescription if greater than 1.5 inches. Assess current level of physical activity and exercise, and past history of eating disorders, in all patients. Social behaviors such as tobacco abuse or excessive alcohol are both positively correlated with bone loss and should be noted (81). The importance of the social history cannot be overemphasized, especially in the elderly, who may have history of frequent falls, require assistive devices or personnel in their living environment, or need consideration for transitional care unit placement. Inadequate daily calcium intake and exercise, vitamin D deficiency, corticosteroid use, diabetes mellitus, and multiple

**TABLE 39.5** Laboratory Tests in Disorders of Calcium Metabolism

Disorder	Serum Calcium	Serum Phosphate	Vitamin D Hydroxy	PTH	1,25(OH) <sub>2</sub> Vitamin D	Urine Calcium	Renal Function
Primary hyperparathyroidism	↑	↓	Variable	↑	↑	Normal ↑	Variable
Familial hypocalciuric hypercalcemia	↑	Variable	Variable	↑	Normal	↓↓	Variable
Hypercalcemia of malignancy	↑	Variable	Variable	↓	Normal	↑	Variable
Vitamin D deficiency	↓ or normal	↓ or normal	↓↓	↑ or normal	Usually normal	↓	Variable
Renal osteodystrophy	↓	↑	Variable	↑↑	↓	↓	↓↓
Primary hypoparathyroidism	↓	↑	Variable	↓	↓	↓	Variable

Note: While 25 (OH) vitamin D levels are variable in many disorders, low levels are very common in general. Renal function is often normal in the various disorders, but it may be decreased. Patients may have more than one disorder. For example, some patients with primary hypoparathyroidism may also be vitamin D insufficient, leading to further elevation of serum PTH.

**TABLE 39.7** Major Risk Factors for Falls

	Risk Reduction Strategies
<b>Demographic</b>	<b>See corrective strategies below</b>
Advanced age	
Female gender	
Previous falls	
Functional Deficits	
<b>Environmental</b>	
Insufficient lighting	Light hallways, stairs, entrances, bathroom
Obstacles in walking path	Clear clutter/loose cords; move furniture
Loose throw rugs	Anchor or eliminate rugs
Lack of assistive devices in bathroom	Install grab bars; high commode seat
Slippery outdoor conditions	Sturdy shoes; assistive device
Wet bathroom and kitchen floors	Nonskid mats; grab bars; tub bench/chair
Improperly fitting shoes, slippers	Encourage use of sturdy, low-heeled shoes
Uneven terrain, cellar stairs	Stair rails; cane/walker
House pets	
<b>Neuromuscular</b>	
Poor balance	High level balance challenge exercises
	Cane or walker; tai chi
Sarcopenia	Resistive exercise; optimize vitamin D levels
Kyphosis	Optimize myofascial release/postural training
Reduced proprioception	Sturdy footwear; balance training; cane/walker
Impairments:transfer/mobility	Mobility training
<b>Medical</b>	
Poor vision	Annual visual examination
Urinary urge incontinence	Medication; timed voids; avoid PM fluids
Orthostatic hypotension	Hydrate; optimize medications
Medication (i.e., for pain, HTN, seizures)	Annual medication review
Depression, anxiety, agitation	Counseling support; medications
Alcohol (>3 drinks/d)	Counseling; abstinence
Malnutrition	Nutritionist; Home Health Nursing Consult
Fear of falling	Mobility training; counseling

Adapted from data from the National Osteoporosis Foundation, 2002–2009.

myeloma are common in the elderly. Inquire into pending dental procedures, as dental extractions could delay start-up of bisphosphonates, the most commonly prescribed medication class for osteoporosis, due to risk of osteonecrosis of the jaw (82,83). History of certain malignancies may be a relative contraindication for teriparatide, a potent anabolic treatment option.

A thorough physical examination establishes cognitive status, assesses oral hygiene and hydration status, and excludes causes of secondary osteoporosis (e.g., hemiplegia, rheumatoid arthritis, anorexia, spinal cord injury). One must assess for pre-existing fractures; for example, multiple vertebral fractures can induce severe kyphosis, with anterior-posterior widening of the rib cage, increasing its proximity to the iliac crests, and inducing abdominal protuberance (49). Document any risks for fall (i.e., visual disturbance, neurologic deficits, contractures, leg length discrepancy, poor balance with transfers, gait abnormalities, and improper use of assistive devices). Evaluate the potential for safe weight-bearing and resistive exercise (i.e., cognitive status, cardiopulmonary status, posture, degree of kyphosis, balance and pain with active and resisted motion).

Document height and weight, contracture limitations and leg length discrepancies after measurement. Assess the general mobility of spine and joints of the extremities, as well as abdominal, spinal, and extremity muscle strength. Verify sites of pain (i.e., vertebrae T8-L2 are associated with osteoporosis, whereas fractures at T6 or above are more likely associated with malignancy) (49). Assess for tibial tenderness in thin, female runners, especially with irregular or absent menses, as seen in FAT. Identify any risks for intolerance of prescription medications; for instance, poor dentition, history of gastric disorder such as GERD, gastritis or peptic ulcer, or diffuse myalgias can delay or preclude bisphosphonate use.

Proximal muscle weakness and chronic corticosteroid use will require special exercise focus. Proprioception, balance, transfers and gait must be evaluated. Proper use and design of assistive devices should also be addressed. Specific physical performance measures that correlate with higher bone mass density in hip and spine, wrist or whole body in postmenopausal women include longer step length, normal and brisk gait speeds and step length, longer single leg stance and grip strength (84).

**TABLE 39.8 Basic Osteoporosis Laboratory Tests**

Complete blood cell count

Thyroid function test
24-h urine calcium
Urine markers for bone resorption-urine NTX <sup>a</sup>

<sup>a</sup>Serum NTX can be substituted.

Evaluation of these parameters and improving where possible with resistive exercises may improve bone mass parameters.

A basic laboratory evaluation is listed in Table 39-8. In primary osteoporosis, results of laboratory tests typically are normal (except 25-hydroxyvitamin D); the primary role of blood and urine tests is therefore to exclude other diseases and in a few cases of urinary NTX, to establish baseline bone turnover rate. For example, multiple myeloma should be suspected with anemia, abnormal serum protein electrophoresis (SPEP), and elevated B-cell population in complete blood cell count. Vitamin D deficiency is best evaluated by serum 25-hydroxyvitamin D. Serum IgA antitissue transglutaminase and IgA endomysial antibody, if positive, can be an indication

of malabsorption (i.e., celiac disease). Low urinary calcium to creatinine ratio or a 24-hour urinary calcium are less specific measures of malabsorption in some cases.

Vitamin D deficiency may lead to secondary hyperparathyroidism. Severe vitamin D deficiency causes osteomalacia, with bone pain and poor mineralization of bone. More commonly, milder degrees of vitamin D deficiency lead to decreased gut absorption of calcium and in some cases secondary hyperparathyroidism, causing loss of bone mineral. Many osteoporosis patients have some degree of vitamin D inadequacy. Vitamin D deficiency also has an effect on muscle, leading to decreased lower body strength and increased propensity to fall. If 24-hour urine calcium value is low, inadequate calcium intake or absorption, or vitamin D deficiency, is likely. If urine calcium value is high, either dietary calcium excess or idiopathic hypercalciuria is a possibility. If the serum calcium is elevated, measurement of PTH is the most important test to do. Primary hyperparathyroidism leads to bone loss and must be differentiated from familial hypocalciuric hypercalcemia (FHH), a benign abnormality of the calcium receptor. Patients with FHH have mild elevations of serum calcium and PTH but very low urinary calcium excretion. It should be noted that patients with primary hyperparathyroidism may have vitamin D deficiency, leading to secondary hyperparathyroidism as well. See Table 39-5, Laboratory Tests in Disorders of Calcium Metabolism.

DXA screening is of value in the individual patient with history of spine or hip fragility fracture, or two or more risk factors for low bone mass. (See Fig. 39-3, Osteoporosis

**FIGURE 39-3.** Osteoporosis Management Algorithm.\*

\*This algorithm is an overall plan for evaluation of women for osteoporosis. It is generally based on the 2008 NOF Clinician's Guide to Prevention and Treatment of Osteoporosis. Each patient must be assessed individually. Clinical judgment remains very important in the assessment and management of osteoporosis.

HOME CALCULATION TOOL PAPER CHARTS FAQ REFERENCES

## Calculation Tool

Please answer the questions below to calculate the ten year probability of fracture with BMD.

Country : US(Caucasian) Name / ID :

About the risk factors 

### Questionnaire:

- Age (between 40-90 years) or Date of birth  
Age:  Date of birth: Y:  M:  D:
- Sex ☐ Male ☒ Female
- Weight (kg)
- Height (cm)
- Previous fracture ☒ No ☐ Yes
- Parent fractured hip ☒ No ☐ Yes
- Current smoking ☒ No ☐ Yes
- Glucocorticoids ☒ No ☐ Yes
- Rheumatoid arthritis ☒ No ☐ Yes
- Secondary osteoporosis ☒ No ☐ Yes
- Alcohol 3 more units per day ☒ No ☐ Yes
- Femoral neck BMD  
T-score

BMI 21.1  
The ten year probability of fracture (%)

**with BMD**

Major osteoporotic	9.7
Hip fracture	1.1

Management Algorithm for defining DXA screening candidates.) If osteoporosis is found by DXA, treatment is indicated. For those patients with osteopenia, the WHO FRAX questionnaire (Fig. 39-4) can be used to determine if prescription medications are needed for improving bone mass. If DXA/FRAX analysis indicates that fracture risk is 3% or more at the hip, or 20% or more at other sites, more aggressive prophylactic therapy (e.g., bisphosphonate) is recommended. If bone mass measurements at the spine, hip, and wrist are normal by DXA, increased exercise, a diet rich in calcium, and calcium and vitamin D supplements may be sufficient fracture prophylaxis, in conjunction with fall reduction training. Such patients should have a repeat DXA in 2 years, with recalculation of the fracture risk via the FRAX tool at that time if osteopenia persists.

Iliac crest bone biopsy is used primarily to exclude osteomalacia or other metabolic bone diseases, such as is seen with late-stage renal failure. Although such biopsies can be used to define high and low bone turnover, this is not usual practice at this time for the typical patient with osteoporosis.

Educational materials can be provided to all patients to reinforce the importance of maintaining bone health, understanding the sequelae of untreated osteoporosis, identifying sources of dietary calcium, and improving fall risk in the home at the time of office visit (<http://www.nof.org/>).

## PREVENTIVE STRATEGIES FOR PATIENTS AT RISK

In the last decade, efforts to improve bone health have focused on prevention and treatment protocols. Prevention programs focus on adequate nutritional status, including optimization of calcium, vitamin D and protein intake, and monitoring for excessive fats or carbohydrate intake. Avoidance of lifestyles known to result in bone loss, including cigarette smoking, excessive alcohol, and possibly carbonated beverage intake is also important. Weight-bearing and strengthening exercises, and fall prevention strategies in the home and community, are equally important.

Because bone mass is the principal, although not the only, determinant of fracture risk, preservation or improvement of bone mass via pharmacologic means is associated with a reduced risk of fracture. The rationale of the various therapeutic agents available for preserving or improving bone mass density or bone mass is based on knowledge of bone remodeling. In normal bone, there is no net change in the amount of bone mass present, as on-going bone remodeling is a balance between bone resorption, and the process of bone formation. In most forms of osteoporosis, however, a perturbation of bone remodeling occurs. Bone resorption increases over normal levels, and bone formation does not compensate for this increase, with a net loss of bone mass overall.

## Nutritional Adjuncts

### Calcium

Dietary and supplemental calcium intake is a mainstay of osteoporosis prevention and treatment. The Surgeon General's

Report on Bone Health and Osteoporosis (2004) recommends calcium intake of 1,200 mg/day in two or more doses for both men and women more than 50 years of age; children require 500 to 1,300 mg/day, dependent on age (Table 39-9). Food sources such as dairy products, dark green vegetables, salmon, and enriched cereals are rich in calcium (85). (See Table 39-10, Selected Food Sources of Calcium, for a more detailed list of food and beverage sources of calcium.)

Calcium supplementation alone has been documented to produce sustained reduction in the rate of loss of total body BMD in healthy postmenopausal women (86). In healthy, older, nonosteoporotic men, a recent study documented less falls and increased BMD of 1% to 1.5% at all sites in men receiving 1,200 mg calcium supplement daily over those receiving placebo. However, vascular events tended to be more common in the experimental group during the 2-year study (87). Calcium supplementation is inexpensive, relatively simple to ingest, and generally safe for most patients (i.e., in the absence of end-stage renal disease, a history of previous kidney stones, or idiopathic hypercalciuria). Despite the relative ease of obtaining daily calcium requirements, average dietary intake is approximately 700 mg/day (86). In past studies, no more than 1% of men and women more than 70 years of age are meeting their calcium requirements from food sources (88). The immobilization that occurs with hemiplegia and paraplegia, if coupled with excessive calcium intake, may result in elevated urinary calcium levels. A predisposition for kidney stones and nephrolithiasis may then be seen. In general, a urinary calcium excretion of up to 250 mg/day is acceptable in individuals without a history of kidney stones (89–92). High sodium intake, as is commonly seen in the United States, can lead to increased urinary calcium loss. Early studies of calcium metabolism suggest that one additional gram of sodium per day above Recommended Daily Allowance (RDA) decreases bone density by 1% per year in women (93,94).

**TABLE 39.9 Recommended Daily Calcium Intake**

Age or Life Stage	Adequate Calcium Intake (mg/d)
0–6 mo (human milk content)	210
7–12 mo (human milk + solid food)	270
1–3 years	500
4–8 years	800
9–18 years	1,300
19–50 years	1,000
>50 years	1,200
Pregnancy or lactation	
≤18 years	1,300
19–50 years	1,000

**TABLE 39.10** Selected Food Sources of Calcium

Food, Standard Amount	Calcium-mg	Calories
Fortified ready-to-eat cereals (various), 1 oz	236–1043	88–106
Plain yogurt, nonfat (13 g protein/8 oz), 8-oz container (low-fat <sup>a</sup> )	452(415)	127(143)
Soy beverage, calcium fortified, 1 cup	368	98
Fruit yogurt, low fat (10 g protein/8 oz), 8 oz	345	232
Orange juice, fortified, 1 cup	308–344	85
Swiss cheese, 1.5 oz	336	162
Sardines, Atlantic, in oil, drained, 3 oz	325	177
Fat-free (skim) milk, 1 cup <sup>a</sup>	306	83
1% low-fat milk, 1 cup (whole milk <sup>a</sup> )	290(276)	102(146)
Plain yogurt, whole milk (8 g protein/8 oz), 8-oz container <sup>a</sup>	275	138
Tofu, firm, prepared with nigari <sup>b</sup> , ½ cup	253	88
Mozzarella cheese, whole milk, 1.5 oz	215	128
Pink salmon, canned, with bone, 3 oz	181	118
Collards, cooked from frozen, ½ cup	178	31
Molasses, blackstrap, 1 tbsp	172	47
Soybeans, cooked, ½ cup, green (mature)	130(88)	127(149)
Ocean perch, Atlantic, cooked, 3 oz	116	103
Oatmeal, plain or flavored, instant, fortified, 1 prepared packet	99–110	97–157
Pizza, cheese	100	255
White beans, canned, ½ cup	96	153
Broccoli (raw), 1 cup	90	25
Okra, cooked from frozen, ½ cup	88	26
Ice cream, vanilla, ½ cup	85	135

Source: Nutrient values from Agricultural Research Service (ARS) Nutrient Database for Standard Reference, Release 17. Adapted from 2002 revision of USDA Home and Garden Bulletin No. 72, Nutritive Value of Foods. Food sources of calcium ranked by mg of calcium and calories per standard amount. Bioavailability may vary. (All dairy are ≥20% of AI for adults 19–50, which is 1,000 mg/d.)

<sup>a</sup>Calcium content varies slightly by fat content; the more fat, the less calcium the food contains.

<sup>b</sup>Calcium content is for tofu processed with a calcium salt; other salts do not provide significant calcium. See <http://www.nal.usda.gov/fnic/foodcomp/Data/SR20/nutrlst/sr20a301.pdf> for a more comprehensive list of foods containing calcium.

## Vitamin D

Vitamin D facilitates absorption of calcium and mineralization of bone. It is found in liver, fatty fish, egg yolks and as an additive in foods such as milk, orange juice, and cereals. It can be taken as a supplement and is also synthesized in the skin through sunlight exposure. As many experts believe that the recommended dietary intake should be higher for children and younger adults, the Institute of Medicine is likely to raise the Recommended Daily Allowance for this vitamin, with final recommendations expected in 2011. Current recommendation for daily intake among experts in the field is 800 to 1,000 IU/day of vitamin D<sub>3</sub> for men and women age 50 or older (95). The active form of vitamin D (1,25-dihydroxy vitamin D or calcitriol) is also beneficial in osteoporosis and is commonly prescribed as a supplement for patients who lack the 1- $\alpha$ -hydroxylase enzyme because of severe renal impairment. Cholecalciferol (vitamin D<sub>3</sub>) is probably the preferred form of vitamin D supplement, but ergocalciferol (vitamin D<sub>2</sub>) can also be used as an oral dose of 50,000 IU, weekly, for 4 to 12 weeks as replacement therapy when low vitamin D levels are found. Severe deficiency can lead to secondary hyperparathyroidism, osteomalacia or rickets, and is associated with increased risk of osteoporotic fracture (96,97).

As these supplements increase calcium absorption at the gut level, their use can result in an increased risk for kidney stones or for hypercalciuria, nephrolithiasis, or even nephrocalcinosis in patients at risk. Increased urinary calcium is the first sign of such toxicity and is easily evaluated with a 24-hour urine sample. Many institutionalized and house-bound elderly patients are deficient in vitamin D and can benefit from its administration (91,92,98,99). In general, total daily administration of vitamin D should not exceed 2,000 IU (100). As most studies have focused on postmenopausal women and the elderly, more research is needed in vitamin D effects on children, premenopausal females, men, and diverse ethnic and racial groups (101). Although there is evidence of benefit of vitamin D supplementation in rickets, hyperthyroidism, fall reduction, and BMD, standardization of 25(OH) vitamin D assays has not been achieved. The effect of sunscreen on activation of vitamin D, and determination of optimal sunlight exposure without increased risk of skin cancer, requires further investigation (102). As calcium and vitamin D are critical to the action of bisphosphonates, normal levels must be verified prior to start of bisphosphonate therapy.

### Protein

Along with calcium and vitamin D supplementation, protein supplementation has been shown to improve healing and decrease mortality in persons who have sustained hip fractures. In a study by Schurch et al. (103), elderly patients received dietary protein supplements of 20 g/day for 6 months following hip fracture. Much of the rapid bone loss that usually occurs in the contralateral hip during the year after a fracture was avoided in these patients. The RDA for protein is 46 g/day for women and 56 g/day for men. This can be achieved with two to three servings of meat or beans, and two to three servings of milk and cheese per day (104). Too much protein, however, may be harmful, as it can incur an acid load; calcium from bone is a major source of serum alkaline buffering in this instance.

### Exercise

A lifelong dedication to physical activity (60 minutes daily for all children aged 8 and older, and 30 minutes for adults) (105) and exercise is recommended. Therapeutic exercise is an essential element of the rehabilitation program for patients with osteoporosis, and should be tailored to the patient's level of fitness and anticipated propensity to fracture. Exercise increases muscle and bone strength, joint flexibility, and balance, and prevents falls. Although genetic factors can determine a large proportion of bone mass and structure, up to 50% to 90%, controllable lifestyle factors contribute as well (106). A thorough history and physical examination and, if appropriate, bone density testing, can address deficits and define exercise precautions to avoid injury. An exercise program should incorporate both short- and long-term goals, which must be reviewed with the patient. Patient education concerning proper posture, body mechanics, and increasing strength and aerobic capacity is an essential component of both short-term and long-term interventions. Osteoporosis is a disease that is progressive and, if unchecked, can cause severe disability. In patients with physical disabilities, inactivity can be especially harmful because of a propensity for further deterioration with aging, and concomitant health problems. The PASIPD questionnaire (Physical Activity Scale for Individuals with Physical Disabilities) can be useful in assessing levels of activity in the persons with disability, such as home maintenance function, moderate and vigorous sport and recreation activities, occupation, and transportation (107).

For optimal bone health, an exercise program should include weight-bearing activities for 45 minutes 3 or 4 times per week, or weight lifting for 20- to 30 minutes 2 or 3 times per week (49). Weight-bearing, low-impact activities include walking or treadmill use; jogging, tennis, and soccer are high-impact activities. Muscle-strengthening activities such as jumping, weight lifting, and use of resistive equipment would be classified as moderate to vigorous activity. Swimming is beneficial from a cardiovascular standpoint, but is not a weight-bearing sport, and thus does not contribute to bone mass (108). Swimming does maintain muscle mass, however, which contributes to fall reduction. Balance training should be included to prevent falls for patients with fall risks

(see Table 39-7). Regular exercise has been shown to improve bone mass (0.5% to 3.0%), with 20% to 45% reduction in hip fractures in older populations with moderate-to-vigorous physical activity (49,109–111). Further investigation is needed to ascertain the complex relationships between physical activity, bone mass, and osteoporotic fractures.

The following general principles should be considered when recommending therapeutic exercise.

### Life Span Bone Phases

Bone health is determined by many factors (112). Increased physical activity, especially weight-bearing and resistive exercise, stimulates bone building via the piezoelectric effect of contracted muscle on bone. In defining general life phases in which bone changes are likely to occur, the clinician can target screening and exercise recommendations more easily. During childhood and adolescence, bone undergoes a *growth phase*, especially during puberty. This is followed by a *maintenance phase* during young and middle adulthood. A *mid-life phase*, ages 50 to 70, can be characterized as a bone loss phase; after age 70, a *frailty phase* is more likely. CDC surveillance data report about 16.7% of adults aged 45 to 64, and 23.1% of adults aged 65 to 74 are inactive. As Americans age, their participation in physical activity declines, with women persistently lagging behind men: 61% of adults reporting never engaging in vigorous physical activity, with 66% of women compared to 56% of men in this category of inactivity (113). Lower levels of physical activity (lack of vigorous exercise) correlated with lower levels of education (80% of those without high school diploma vs. 43% of those with bachelor's degree or higher) and lower income (72% of poor families compared with 52% of families classified as not poor) (114).

The most critical period of bone growth is thought to be during puberty and adolescence, with the most gains, on average 25% to 30% of adult bone mass, between age 12 to 14 in girls and 13 to 15 in boys (115). Most of these gains reflect increased bone length and size, not bone density (116). Bone mass gained during this period was found to typically equal to the amount lost later in adult life (117). As bone mineralization lags behind growth in length, fracture rates increase during periods of rapid growth (118). In a school-based program that emphasized jumping activities over 7 months, only early pubertal girls improved in bone mass (1.5% to 3.1% at the femoral neck and lumbar spine when compared with controls), with no benefit noted in the late prepubertal experimental group of girls (119).

Exercise need not be strenuous to confer benefit (120–122). The gentle, slow movements involved in the practice of t'ai chi have been gaining in popularity with the elderly. Benefits have been reported in balance, strength, cardiovascular fitness, respiratory function and flexibility, and decreased injury. Wolf et al. reported a 47.5% decrease in multiple falls in assisted living residents aged 70 to 97 during a 1-year program for elderly patients (123). Li et al. demonstrated a 55% reduction in multiple falls, and reduced injury from fall (7% vs. 18% in controls) with a three times weekly t'ai chi program during a 6-month period (124). Later studies demonstrated delayed bone density

loss in postmenopausal female t'ai chi practitioners (125–127). Early research in whole body vibration also shows preliminary benefit in balance in residents of long-term facilities (128), muscle strength (129,130), and bone mass (130).

### Exercise Principles

The following general principles should be considered when recommending therapeutic exercise (131).

#### *Principle of Specificity*

Exercise should stress the specific physiologic system being trained. In patients with normal bone mass, exercise activities should stress sites most at risk for fracture (i.e., the hip, spine, and wrist). Exercise for osteogenesis may be prescribed for the purposes of prevention of osteoporosis even for those with minimal reductions in bone mass. High-impact exercise such as jumping and strength training is more beneficial to improving bone mass than low-to-moderate intensity exercise such as brisk walking, and has positive bone mass effect at spine and hip, in as little as 5 to 10 min/day (132). However, these exercises may not be appropriate for the frailty-phase patient population, because patients with very low bone mass and multiple fractures need skeletal protection while building strength, and increasing balance and flexibility. Isometric, core-strengthening exercises with the spine in neutral position should be emphasized in all patients; spinal flexion should be avoided in those patients with abnormal mineral density, particularly the frail (133).

#### *Principle of Reversibility*

The positive effect of exercise will slowly be lost if the program is discontinued. Hence, a lifelong dedication to exercise and physical activity is necessary for optimal bone health, as changes associated with aging can have profound physical and clinical consequences. On average, adults lose 5% of muscle mass per decade after age 30, with more rapid decline possible after age 65 (134). However, many patients with sarcopenia (age-related loss of skeletal muscle) and impaired balance remain highly functional. This muscle loss may be reversed by exercise—as shown by Fiatarone et al. (135). A comprehensive exercise program must increase bone mass and muscle strength (136) with continued variety to prevent abandonment of exercise goals. It is important to emphasize strengthening the bone while it still has adaptive ability; this is particularly important in persons with disability and the elderly. While passive standing is not recommended for active adults for exercise, in a person with severe disability such as spinal cord injury, through the use of a standing frame or standing wheelchair, it is a rehabilitative strategy shown to prevent bone loss (137).

#### *Principle of Progression*

To increase bone mass, the stimulus must exceed previous bone-loading activity. Thus, there must be a progressive increase in the intensity of the exercise for continued improvement. Kerr's study of resistive exercises at the hip demonstrated that exercise benefits are site specific and result from progressive resistance exercise with maximum loading as opposed to an endurance regimen

(138). To avoid injury, however, applied loads must be within the capacity of the bone to sustain mechanical stress. Progressive resistance is important for both bone health and improved functional capacity (139). Slowly increasing time or intensity of exercise by 10% weekly decreases risk of injury (140).

#### *Principle of Initial Values*

Those who initially have low capacity will have the greatest functional improvement from a given program (141). Nevertheless, it is important for inactive participants to begin with short exercise sessions of low intensity and progress systematically to limit risk of injury.

#### *Principle of Diminishing Returns*

There is a biologic ceiling to exercise-induced improvements in function. As this ceiling is approached, greater effort is needed to achieve minimal gain.

Optimal calcium intake is thought to be synergistic with physical activity throughout life in improving bone mass (142–144) and should be encouraged in all patient populations where medical contraindications do not coexist. In meta-analysis of randomized clinical trials, Shea et al. concluded that calcium supplements in postmenopausal women reduced bone loss by 2%, with an approximate 23% reduction in spine fractures (145). Vitamin D supplements may reduce spine fractures by as much as 7% (146). Exercise must also be supported with adequate caloric intake for energy expended for all patients, as indicated by adequate glycemic index. Weight loss, which sacrifices adipose tissue and depletes estrogen production stores sufficiently to cause amenorrhea in females, increases the risk of osteoporosis and stress fractures. More than 3 months without menstruation should prompt clinical evaluation in these patients (see Female Athlete Triad [FAT], below).

The prevention of falls and fractures through an ongoing exercise program that maintains proper nutrition, strength, and aerobic capacity should be coupled with adjunctive measures such as the provision of adequate support for the spine, pain management, and psychological support when developing objectives for long-term goals.

### Fall Reduction Strategies

Approximately one-fourth of community-dwelling persons 65 years of age will fall (147); this number doubles for residents in nursing homes (148). Although less than 1% of falls result in fracture, according to the Northeast Hip Fracture Study Group, 90% of hip fractures are due to a fall (149). The propensity to fall may be as important as bone mass, given the frequency and severity of falls in this age group. Falls have many etiologies, including decreased neuromuscular coordination of the elderly (resulting in an inability to prevent loss of balance or break a fall's impact), mental status issues such as confusion and dizziness with medication, and environmental factors such as poor lighting and loose rugs. New research has examined differences in frequency, mechanism, and risk factors for falling between men and women ("<http://www.cdc.gov/ncipc/factsheets/nursing.htm>") (150). The loss of muscle mass can be as much as 3% to 5% per decade after

age 30, and is also commonly associated with falls and fracture in the elderly. Fiatarone et al. found 71% of elderly hip fracture patients were sarcopenic (151).

Degree of demineralization of bone and the trauma of falling are well established as risk factors for fracture. There are rare reports of spontaneous hip fracture, although one historical study in 1981 demonstrated that 11% of fractures were spontaneous, with 25% of them associated with standing or sitting transfers and 60% during simple ambulation (152). More research is needed in this area. These studies support the notion that fractures of the proximal femur can be the result of muscle forces acting on the hip exceeding the mechanical ability of the femur to withstand stress (153). Because hip fractures have multifactorial causes (154), interventions must aim not only at increasing BMD at the hips, but also at increasing muscular strength, balance, and flexibility and reducing the forces of impact when a fall occurs.

A successful program aimed at preventing falls includes education on how to eliminate identifiable fall risks, and exercises that prevent falls through improved balance, such as gait training, coordination and functional exercises, and muscle strengthening (155–157). Preservation of autonomy after a fracture can be aided by modifications made to the home environment before the patient is released from the hospital. Home visits from an occupational therapist have also been shown to be helpful in this regard (158).

Falls in long-term care facilities present very specific challenges. According to the CDC, approximately 5% of adults age 65 and older live in nursing homes in the United States, and about three out of four of these residents fall each year, which is twice the rate of older community dwellers. About 2% to 6% of these falls result in death. The most common causes of these falls are similar to those of community dwellers listed above. The most effective strategies to prevent falls include post-fall assessment and follow-through on findings; staff education; medication review; environmental changes such as raised toilet seats, lower bed height and hallway handrails; hip pads; bed alarms. Physical restraints do not lower fall risk, and in fact, may increase the risk of injury and death with falls (150).

### Mechanisms of Falls

Although much attention has been given to methods for increasing bone density, the scientific literature on mechanisms behind falls is less studied; Hayes and Cumming have contributed much in this area (152,159–162). The severity of the fall is an independent risk factor for hip fracture (163) and is related to many factors, including the direction of the fall and the specific anatomic location of major impact (161). Whereas young adults tend to fall to the side or backward, the elderly tend to fall sideways or drop in place, especially those with unsteady gaits (159). It is falls to the side that result in major impact forces that greatly exceed the mechanical strength of the proximal femur and therefore result in fracture.

The risk of falling appears to increase linearly with the number of risk factors present. The most consistent predictors for falling include balance and gait abnormalities, impaired

vision, decreased ADL function, polypharmacy, and cognitive impairment (147). Sedative use, particularly polypharmacy, is associated with falling independent of other risk factors. Benzodiazepines, phenothiazines, and antidepressants are used frequently in the elderly for dementia and depression, and use of these medications is associated with increased falling—particularly when taken in their longer-acting forms. Diuretics and antihypertensive agents are also associated with an increased risk of falling, as they can induce postural hypotension. An annual review of current medications, especially antihypertensives, psychotropics, sedatives, analgesics, antihistamines, and diuretics, should be included in fall risk assessment screening. Table 39-7 lists other major risk factors, including environmental hazards.

### Fear of Falling

The elderly have a generalized fear of falling and are particularly fearful of not being able to get up after a fall. In comparison to fallers who were able to get up, Tinetti found that those unable to get up were more likely to suffer permanent decline in ADLs, be hospitalized more frequently, and have a higher mortality rate. The highest risk factors in this group were age greater than 80, depression, and problems with balance and gait (164). It is reasonable to expect fear of falling in the elderly, to see it reduce physical activity and conditioning, and thus become an independent risk factor for falling (165). Velozo modified the University of Chicago Fear of Falling Measure (UIC FFM) using Rasch analysis to develop a successful unidimensional construct that links a community-dwelling older person's level of fear with functional activities, such as “stepping off a curb” or “standing on a moving bus” (166). This assessment can be useful in defining rehabilitative interventions in different population groups. Table 39-11, Fear of Falling Measure, lists the activities with clinical relevance.

For a fall to result in hip fracture, there must be impact near the hip that is not reduced by body mechanisms or absorbed by soft-tissue structures. The fall itself may be divided

**TABLE 39.11** Fear of Falling Measure<sup>166</sup>

1. Walk when icy
2. Carry bundles up poorly lit stairs
3. Use a step stool to reach in kitchen cabinet
4. Climb poorly lit stairs
5. Stand on a moving bus
6. Climb up bus stairs
7. Get in/out of bathtub
8. Carry bundles up well-lit stairs
9. Step off a curb onto the street
10. Walk on a crowded sidewalk
11. Climb up well-lit stairs
12. Use an escalator
13. Take a walk
14. Get in/out of a car
15. Carry a full plate to the dinner table
16. Pick something lightweight from the floor

into four phases (162,166): instability phase, where balance is lost; descent phase; impact phase; and post-impact phase.

A fall prevention program should address these four phases of a fall and present interventions at each level (167). General conditioning exercises, appropriate provision of assistive devices, adequate footwear, modification of medications, and attention to other risk factors for falling are targeted at preventing the instability that results in a loss of balance (168). There is ample evidence of the benefit of exercise increasing bone mass and preventing falls. These programs must be maintained, however, for continued benefit to accrue to bone mass and muscle strength (169). Several important determinants govern the forces applied to the femur as a result of falling. These forces include the person's weight, thickness of subcutaneous tissue, height of the fall, configuration of the body during the fall, velocity at which the hip strikes the impact surface, and nature of the impact surface. *Falling to the side raises the risk of hip fracture approximately sixfold, compared with the threefold increase in relative risk associated with a decrease of 1 SD in hip BMD (152,159–161).* Contraction of the quadriceps and other muscles of the lower limb is likely to reduce velocity at impact and reduce impact forces at the proximal femur in falls to the side. Exercise programs aimed at increasing lower-extremity strength may therefore prevent hip fracture by reducing fall severity (138,164,169–172).

Meta-analysis by Moayeri et al. demonstrated that moderate to vigorous physical activity is associated with hip fracture risk reduction of 38% in women and 45% in men (173). Low body weight and low BMI are associated with an increased risk of hip fracture in elderly men and women (154,163,170,171). Although the impact force most closely correlates with the individual's weight, velocity on impact is most associated with height. Thus, although an individual may be heavier and the resultant force of impact more, he or she may have more padding over the trochanter in addition to stronger bone, thereby preventing fracture.

While the benefits of physical activity and exercise are well described, it is less clear which exercises are most efficacious in preventing falls and decreasing risk of osteoporotic fractures (174,175). Since weight-bearing exercises lead to site-specific improvement in BMD (176), it is reasonable to hypothesize that upper extremity strengthening and core strengthening would play a significant role in fall and fracture prevention, and improve overall function and general fitness, as lower extremity exercises have been shown to do. Evidence from the Tromsø study suggests, however, that among middle-aged women, a high level of physical activity is related to increased risk of fracture at non-weight-bearing sites, including the wrist, proximal humerus, hand, and fingers (177). Carter et al. addressed the effects of improved resistance and agility training, but found no benefit in reducing fall risk in osteoporotic women aged 65 to 75. However, although trunk stabilization exercises were included in this "Osteofit" exercise program, only knee extension strength was evaluated as a measure of improvement in fall risk (178). Liu-Ambrose et al. however found decreased fall risk (37.4% to 43.3%) with regular exercise in women with low bone mass aged 75 to 85, but less increase in physical

activity from resistive exercise (3.8%) than balance (29.2%) or stretching exercise (37.7%) (179). Thus, there is a clear need for further research in clarifying the relationship between specific exercise protocols and their contribution to fall and fracture reduction.

Recognition that increases in soft-tissue thickness around the hip substantially reduce peak force to the trochanter at fall impact has led to the development of hip protectors. Fractures have been prevented in women wearing hip protectors, and Lauritzen concludes that the use of hip protectors could reduce fracture by 53% (172). The Cochrane Database System Reviews of 2003 and 2007 indicated many trials have identified strategies to prevent falls (180,181), but standardization is lacking for outcome measures. The 2005 Cochrane review by Parker and Gillespie however showed no clear benefit from hip protectors in preventing fractures, citing poor compliance due to discomfort and practicality as important factors (182). Pads are designed in two primary configurations: a simple pad that covers the trochanter and reduces impact force by absorbing energy in the pad material, and one based on shunting energy from the fall away from the trochanter (183). The latter pad is designed in an inverted U shape and is filled with a colloidal-like substance that hardens on impact, permitting 68% reduction in peak force at the hip with impact. Softer pads tend to promote more compliance with wear (184).

Architectural modification of the flooring surface offers an approach to impact reduction that seems worth exploring, particularly in residential health care facilities and housing projects for the elderly. Research has shown that the least number of falls occurs with vinyl flooring, and wooden subfloors decrease the risk of fracture with falls compared with concrete subfloors (185). When compared with linoleum flooring, a thick pile carpet with underpad can reduce impact from a fall by 23%, but this solution seems impractical in light of the difficulties in ambulation presented by rugs of this design (186). Other flooring systems that might provide impact reduction without presenting an obstacle include low-pile carpeting and rubber-backed materials. Caution would have to be taken to air these products thoroughly so as not to introduce a confounding health risk in the form of toxic chemical exposure. There is continued research into shock-absorbent flooring, but it has proven to be expensive and impractical in homes and hospitals already built (185).

### Psychosocial Considerations

Psychological issues have been noted to contribute significantly to disability in the osteoporotic patient after fracture. Depression is the most common psychological problem identified in these patients. A study of community-dwelling postmenopausal women found that those with osteoporosis had significantly higher depression scores than did those with normal bone density (187). Anxiety, fear, and other emotional reactions also affect post-fracture outcome. In a study of 200 women recovering from hip fractures, those with high depression scores following surgery were more likely to experience poorer recovery of function (188). In a 1993 study of 100 women with

osteoporosis-induced vertebral fracture, the women noted emotions as having greater importance than physical functioning, leisure and social activities, and ADLs (189). In this group, most reported fear of falling, fear of new fractures, frustration, anger, and feeling overwhelmed. Vertebral fracture patients also suffered loss of self-esteem, isolation, vulnerability, and embarrassment related to physical appearance (139).

There is increasing evidence that women with depression are more susceptible to low bone mass, with both antidepressant medications and imbalance of immune system inflammatory proteins implicated (190). Inflammatory proteins are induced by adrenalin, which is frequently elevated in depressed. Of these proteins, IL-6 is known to promote bone loss (191). Dudgeon et al. investigated the relationship of physical disability and chronic pain to changes in lifestyle. They found patients learned to suppress pain complaints to some degree because of perceived negative social consequences in the form of isolation, rejection, and consequent depression. Patients' methods for coping with pain included distraction techniques (e.g., listening to music), which conferred some sense of control in a health care system in which the nature of their pain was not well understood, not addressed adequately, and peripheralized by health care providers (192).

## PHARMACOLOGIC AGENTS

The ability of Food and Drug Administration (FDA)-approved pharmacologic agents to prevent or treat osteoporosis has been studied best in postmenopausal women; fracture data are more limited for men and for corticosteroid-induced osteoporosis. Thus, prescription treatments at present demonstrate fracture risk reduction best in those with osteoporosis by DXA and/or fragility fracture history, compared with osteopenic patients without fractures. Benefit and risks of therapy must be individualized to each patient. The therapeutic agents available for the treatment and prevention of osteoporosis are classified as decreasing bone resorption (antiresorptive

agents) or stimulating bone formation (anabolic agents). The end result of each is the same: to preserve or improve bone mass, and thereby prevent fractures. As noted in Table 39-12, Bisphosphonate Comparison, and Table 39-13, Nutritional and Pharmacologic Treatments for Osteoporosis, most U.S. FDA-approved therapeutic agents decrease bone resorption. Reduction of hip fracture may lead to a reduction in mortality. Lyles et al. showed a 28% reduction in deaths from annual infusion of zoledronic acid within 90 days after repair of hip fragility fracture (193). A recent study by Gilchrist et al. with alendronate 70 mg weekly dosing in acute spinal cord injury patients demonstrated significant differences over placebo controls in total body BMD (+5.3%), and total hip BMD (+17.6%) at 1 year (194).

## Antiresorptive Agents

### Bisphosphonates

The FDA-approved bisphosphonates, alendronate (Fosamax), risedronate (Actonel), ibandronate (Boniva), and zoledronic acid (Reclast) have the ability to preserve and increase bone mass at the spine, hip, and other sites to varying degrees, and in most cases prevent fractures at these sites. The FDA has approved their use for the prevention and treatment of osteoporosis for postmenopausal women, and men in most cases. The use of these medications in pediatric populations is promising, particularly in juvenile idiopathic arthritis, but more studies are needed (195,196). Their mechanism of action is well studied: they bind to the surface of bone and are taken up by osteoclasts during the bone resorption process. They subsequently precipitate early cell death by blocking essential lipid compounds within the osteoclast, slowing the resorption process. (See Tables 39-12 and 39-13 for summary of dosing, safety and efficacy of medications in this class and other treatments.)

Long half-life allows some bisphosphonates to accumulate and persist in bone, which promotes maintenance of bone density gains even after treatment is stopped. This permits treatment “holidays,” provided DXA and bone turnover markers remain

**TABLE 39.12 Bisphosphonate Comparison**

Name	Treatment Dose (per d/wk/mo)	Increased BMD Sites <sup>a,b</sup>	Decreased Fracture Sites <sup>a,b</sup>	FDA Indications
Alendronate	10/70/na <sup>a</sup>	Spine, hip	Spine, hip	P <sup>c</sup> , T, M, G
Ibandronate	2.5/na <sup>a</sup> /150 (3 mg IV/3 mo)		Spine	P, T
Risedronate	5/35/150	Spine, hip	Spine Nonspine Hip	P, T, M, G
Zoledronic Acid	5 mg IV yearly	Hip	Spine, non-spine, hip	T, M, G, F

<sup>a</sup>na, not available.

<sup>b</sup>In postmenopausal women.

<sup>c</sup>Dose 5/35/na.

F, post-hip fragility fracture; G, treatment for glucocorticoid-induced osteoporosis, male or female; M, treatment of men with osteoporosis; P, prevention of postmenopausal osteoporosis; T, treatment of postmenopausal osteoporosis.

Data adapted from NOF Clinician's Guide to Prevention and Treatment of Osteoporosis.

\*Note: Definitions are based on WHO assessment of bone mass measurement at any skeletal site in white women (176); data cited for increased BMD and Decreased Fracture Sites are not from comparable studies.

**TABLE 39.13** Nutritional and Pharmacologic Treatments for Osteoporosis

Medication	Usual Dosage	Mode of Action	Side Effects > placebo (≥5%)
FDA Approved <sup>a</sup>			
Calcium	1,200 mg/d	Decreased bone resorption	Increased urinary calcium
Vitamin D <sub>2</sub>	800–1,200 IU/d	Increased calcium absorption	(low risk) hypercalcemia
Or D <sub>3</sub>	—	In GI tract	
Bisphosphonates		Decreased bone resorption	Esophageal irritation (po) Osteonecrosis jaw (IV predominantly, in cancer pts.) atypical femoral fractures
Alendronate (Fosamax)	10 mg daily or 70 mg weekly (space) po (mg daily or 35 mg weekly for osteopenia)		
Risedronate (Actonel)	5 mg daily, 35 mg weekly or 150 mg monthly		
Ibandronate (Boniva)	150 mg po monthly or 3 mg IV every 3 months		
Zoledronic acid (Reclast) <sup>a</sup>	5 mg IV over 15 min yearly		
Postmenopausal women			
Teriparatide (Forteo)	20 µg daily sq (max. 18–24 months Rx)	Increased bone mineralization	Leg cramps; dizziness
Calcitonin (Miacalcin)	200 MR IU/d (nasal spray)	Decreased bone resorption	Nasal irritation (rare)
Estrogen with or without progesterone	0.625 mg/d for 21–30 d (cycled 21 of 30 d)	Decreased bone resorption	Possible increased risk of cancer, high blood pressure, deep vein thrombosis, stroke, heart dis- ease, thromboembolic disease
Estrogen agonist/antagonist			
Raloxifene (Evista)	60 mg/daily	Decreased bone resorption	Hot flashes, leg cramps, deep vein thrombosis
RANKL Inhibition			
Denosumab (Prolia)	60 mg sq twice yearly	Decreased bone resorption via RANKL inhibition	Musc-skel pain, elevated cholest- erol, cystitis pancreatitis

stable. When ingested orally, these drugs must be taken at least one-half hour before any food, drink, or other medication in the morning, and the patient must maintain an upright position during that time to avoid the risk of esophageal irritation and, rarely, ulceration. Other side effects include visual disturbances and difficulty swallowing. Ninety-four percent of the case reports of osteonecrosis of the jaw with this class of drug are associated with cancer patients receiving multiple doses of IV bisphosphonates (83). While in one British study there was a higher risk of atrial fibrillation with zoledronic acid compared to placebo (1.3% vs. 0.4%), this risk is still under investigation with other bisphosphonates and has not led to any FDA-induced change in prescription recommendations (197). Bisphosphonates should be prescribed with caution in patients with severe renal dysfunction and are not considered safe for pregnant women (198). Compliance with medication dosing must be monitored. Siris et al. found only 43% of women over age 45 were compliant with refills of bisphosphonate prescriptions, and only 20% persistent without gaps in refills at 2 years; only compliant patients had significant reductions (20% to 45%) in fractures (199). It must also be stressed to the patient the need for concomitant calcium and vitamin D supplementation to maximize efficacy

of the bisphosphonates, as noncompliance with supplements is also common and reported as low as 40% (200).

### ***RANKL Inhibition***

Research on the remodeling mechanisms involving osteoblasts and osteoclasts has resulted in the development of a new category of anti-resorptive medication, an inhibitor of RANKL (nuclear factor-κB ligand). Denosumab (Prolia) decreases bone resorption by inhibiting the earliest stages of osteoclast maturation. The antibody prevents RANKL from interacting with the receptor RANK, truncating the earliest stages of the osteoclast maturation cascade (See Figure 39-2). Denosumab is administered via subcutaneous injection (60mg) twice yearly. Side effects include musculo-skeletal pain, elevated cholesterol, cystitis, pancreatitis and infection. It is approved for the treatment of postmenopausal osteoporosis.

### **Hormone Therapy**

#### ***Estrogen***

Estrogen is important to bone development throughout life for both men and women. Because it acts on both reproductive and nonreproductive tissues in the body, consideration for use

of its exogenous forms, alone or in combination with progesterone, must balance its benefits with the individual patient's medical and family history. It was first approved by the FDA for postmenopausal osteoporosis in 1972, after approval in 1942 for relief of menopausal symptoms (201). A recent trial by the Women's Health Initiative (202) reported the first definitive data supporting a benefit of postmenopausal hormones in the prevention of fractures at the hip and spine by at least one third compared to placebo. One arm of this placebo-controlled trial involved the administration of an estrogen/progestin combination tablet (0.625 mg estrogen, 2.5 mg progestin [Prempro, Wyeth-Ayerst, Philadelphia, PA]) versus placebo to approximately 17,000 postmenopausal women with an intact uterus. A second arm of the study evaluated estrogen alone in women who had hysterectomies (203). Both studies were halted early because evidence of harm was found in the form of increased incidences of stroke, deep vein thrombosis, and cognitive impairment. Increased risk of coronary heart disease, invasive breast cancer, and pulmonary embolism were found in the combined estrogen/progestin study. The development of these conditions was determined to outweigh the benefits that were achieved in counteracting osteoporosis and preventing colorectal cancer. Despite these concerns, estrogen supplementation continues to be an important part of the overall treatment of osteoporosis in women. Hormone replacement therapy in women is FDA-approved for prevention of osteoporosis only, and is to be taken in conjunction with calcium and vitamin D. Several studies have indicated that withdrawal of hormone therapy can result in decline in bone density and higher rate of hip fracture (204,205). Research with lower-dose hormone therapy and newer "designer estrogens" offers promise of beneficial effects without the detrimental side effects.

### **Raloxifene**

Selective estrogen receptor modulators (SERMs) are now called *estrogen agonist/antagonists* and have been developed to provide beneficial effects similar to those obtained with estrogen, but without the adverse effects. They have an agonistic effect on bone and lipoprotein production, while being antagonistic toward breast tissue, without effect on uterine mucosa. Only Raloxifene (Evista) is FDA-approved in this class, for the treatment of postmenopausal osteoporosis, and prevention of bone loss in recently postmenopausal women; it is not recommended for relief of menopausal symptoms (74). The use of raloxifene provides modest increases in bone mass, but reduction in the risk of vertebral fracture is 40% to 50%, and there is no reduction in nonvertebral fractures (45). It also appears to reduce the risk of estrogen-dependent breast cancer, but increases the risk of deep vein thrombosis to a degree similar to that of estrogen. Newer research in this class focuses on increased benefit to bones, heart and breast tissue (206).

### **Combination Antiresorptive Therapies**

The efficacy and safety of combined bisphosphonates with either hormone therapy or SERMs is being studied; as they have different mechanisms of action, there may be potential

for an additive effect when used together. Bone et al. showed 8% increase in spine BMD in combination, compared to 6% with either alone (207). However, as there is no proven additive effect on fracture reduction, combination therapies are considered experimental (208).

### **Calcitonin**

Calcitonin is a natural hormone secreted by parafollicular cells within the thyroid gland and has an inhibitive effect on osteoclasts. Although the PROOF trial noted a decrease in spine fractures by 33% with 200 IU daily dose, (209), later studies showed no significant difference in nonspine fracture rates after 5 years. Its use subsequently declined. Current research is focused on oral and higher-dose nasal spray forms. It may have limited potential to decrease pain after acute compression fracture in the spine, and has few side effects of significance: nasal congestion, nosebleeds, and nausea.

## **Anabolic Agents**

### **Teriparatide**

The FDA approved the use of teriparatide (Forteo), a recombinant human PTH fragment (PTH 1 to 34) for the treatment of osteoporosis in 2002 after initial studies showed increased absorption of calcium and phosphorus, and a remarkable increase in bone turnover, with bone formation outweighing bone resorption (210). It is administered by subcutaneous injection daily (20 µg, in a preassembled multiple-dose pen device). It has an anabolic effect on bone through thickening of the bone cortex, and increasing connections within the bone matrix. It is approved for treatment of postmenopausal osteoporosis and for men with idiopathic or hypogonadal osteoporosis who are at high risk for fracture, and for those who have failed or are intolerant of previous treatment (74). In postmenopausal women with osteoporosis, BMD increased by 9.7% in the spine and 2.6% at the hip, with fracture reduction of 65% at the spine and 53% at nonspine sites (211). Data for fracture risk improvement in men have not been established, but a 1998 study showed BMD increases of 5.9% in spine and 1.2% at the hip in this population (212). Common side effects include dizziness and leg cramps. Although the approved dose regimen has not been found to increase risk of osteosarcoma in humans as has been observed in laboratory animal studies, this medicine is presently not prescribed for patients with a history of bone carcinoma or bone metastases. Nor is it thought safe in pediatric patients, or adult patients with hypercalcemia, Paget's disease, or kidney disease (213). Neither efficacy nor safety of treatment beyond 2 years is established. Because of the biphasic circadian rhythm of endogenous PTH secretion, and its sensitivity to nutritional intake and growth hormone, there may be novel pharmaceutical treatments in the future in this area (214).

### **Testosterone**

Testosterone is of value only in the treatment of secondary osteoporosis in hypogonadal men. Prostate-specific antigen and serum lipid status should be monitored during treatment.

Anabolic steroids may actually have a beneficial effect on bone mass; however, their side effects include liver toxicity, masculinization, and increased cholesterol levels, which prohibits their use in osteoporosis.

### Cytokines

In theory, a number of cytokines may function as growth factors (transforming growth factor  $\beta$ , IGF-I, etc.) with potential benefit in osteoporosis. Their benefits as established by clinical trials, however, are not presently common in clinical practice, although IGF-I and DHEAS may be used to assess bone health in pediatric populations in the future (i.e., anorexia nervosa and cerebral palsy) (215).

### Non-FDA-Approved Drugs

Current data suggest that high-dose sodium fluoride, which is a positive bone former, may actually worsen osteoporosis by increasing the risk of nonspinal fracture. Whether sodium fluoride in newer formulations, including a low-dose sustained-release preparation, will prove of benefit is unclear. Sodium fluoride must be viewed as an experimental therapy with some concerns regarding its overall benefit in osteoporosis (216–218).

### Other Bisphosphonates

Etidronate, tiludronate, pamidronate, ibandronate, and zoledronate are currently FDA approved for the treatment of such conditions as Paget's disease, hypercalcemia of malignancy, heterotopic ossification, and myositis ossificans. Etidronate is not as potent as the newer bisphosphonates in the treatment of osteoporosis and can also impair the laying down of mineral during new bone formation if given in high doses (219).

## REHABILITATION MANAGEMENT POST-FRACTURE

Osteoporosis is a silent disease that can progress from minimal impairment of the skeleton's capacity to bear stress to a disease characterized by frailty, fracture, deformity, chronic pain, handicap, and loss of independence. Patients present with an individualized spectrum of complaints warranting different degrees of investigation and intervention (see Fig. 39-3). Rehabilitation management depends on accurate determination of the degree of bone loss, the risk factors for osteoporosis, the degree of frailty and propensity to fall, the capacity for participation in ADLs and safe exercise, and pain impairment level. All patients with chronic disability should be investigated for secondary causes of osteoporosis and comprehensive treatment initiated where warranted.

### Radiologic Imaging

Imaging of symptomatic skeletal sites to evaluate for the presence of fractures and ascertain degree of associated deformity may be required. Plain radiographs often suffice to determine site of fracture, but if negative, MRI may be needed to detect first signs of inflammation associated with vertebral microfractures of individual trabeculae. This can determine acuity of

compression fracture or occult hip fracture. MRI is also useful if neurologic involvement is suspected with new compression fracture. For example, severe vertebral collapse can precipitate foraminal narrowing and nerve impingement, or retropulsed bone fragments that may compromise spinal cord function. MRI can also identify avascular necrosis, disc herniations, and facet pathology post-fracture. When MRI is contraindicated or poorly tolerated, CT scan can be performed; it is particularly helpful in identifying metastatic disease, and fracture lines that are potential routes for cement extravasation with vertebroplasty. Skeletal scintigraphy can be also helpful in differentiating acute from chronic compression fracture sites, fracture pain from arthritic complaints, and bone malignancy.

Bone mass measurement with DXA is of value in determining the goals and intensity of the therapeutic exercise program post-fracture. However, if not available, the diagnosis of fragility fracture at the spine or hip also establishes the diagnosis of osteoporosis, to guide medical precautions during the post-fracture rehabilitation phase. When the fracture is healed, DXA can be obtained in most patients and can provide a baseline to monitor response to treatment over time. (See Fig. 39-3, Tables 39-5 and 39-8, and Clinical Evaluation, above, for appropriate screening and treatment guidelines.) Rehabilitation goals include pain reduction, improvement or maintenance of bone mass and muscle strength and flexibility, and establishment of medical precautions for safe exercise, fall reduction (see Table 39-7), and maximum recovery of independence. Strategies to achieve these goals should also address secondary causes for osteoporosis and any deformity, pain, or contractures, while improving core and peripheral muscle strength, balance, and gait.

The plan of care should include appropriate diagnostic tests and pain management strategies, prescriptions where appropriate for osteoporosis medications or supplements (see Tables 39-12 and 39-13), rehabilitation therapy, assistive devices and home modification to prepare the patient for maximum independence in exercise, fall reduction, and safe ADLs. Clearly define all medical precautions for patient and therapists, to prevent injury or medical complications during exercise and ADLs; recommend diet and lifestyle behaviors to optimize bone health (see Fig. 39-3).

Commonly, older patients present with many significant risk factors for low bone mass, and history of previous fractures, with acute or chronic disability. As discussed above, fractures can occur in virtually any bone, but often occur in one of three common sites: distal radius, proximal femur, and/or vertebra due to the biomechanical strategies of falling. The pain associated with these fractures is usually severe but self-limiting. The loss of function resulting from these fractures can be severe, affecting mobility and ADLs, and may lead to loss of independence and to subsequent institutionalization.

As stressed above, screening for calcium intake and vitamin D deficiency is very important in the elderly and in persons with disability, because of the prevalence of vitamin D deficiency in these populations, and the synergistic benefit of calcium and vitamin D in exercise and fall reduction programs. Weight-bearing and progressive resistance exercises targeted to

areas most commonly fractured can increase bone formation at those sites, with consideration of the general fragility of the skeleton individualized for each patient by therapists.

### Vertebral Fracture Rehabilitation Course

Up to 33% of vertebral fractures are silent (see Table 39-2). Although fractures of the proximal femur and distal forearm are associated with significant pain, fractures of the vertebrae can be associated with minimal trauma, such as coughing or straining on the commode, and can be asymptomatic (139). Shen et al. in 2007 estimated that only 20% to 25% of vertebral compression fracture patients seek medical attention (220). Diagnostic procedures, most frequently the radionuclide bone scan or MRI, with STIR (short tau inversion recovery) imaging, may be used in evaluating the acuity of vertebral fractures noted on plain radiographs, particularly with active pain complaints at the site.

Vertebral fractures in the osteoporotic patient typically involve the anterior portion of the vertebral body, and occur most frequently at the thoracolumbar junction, T8 through L2 (221). This portion of the spine is made of predominantly cancellous bone (65% to 75% trabecular and 25% to 35% cortical). The midradius, by contrast, is about 95% cortical bone in content. In primary osteoporosis, one sees decreases in the density of trabecular bone by about 40% by 75 years of age (222).

Most patients with compression fractures present with acute or chronic back pain, and complain of sharp pain that increases with movement, particularly bed mobility and transfers, and is alleviated with rest. After acute fracture, patients can complain of pain with even basic ADLs like walking, combing hair or donning clothing. Severe and frequently disabling pain may persist for 2 to 3 weeks, but usually subsides by 6 to 8 weeks from time of fracture. It is unlikely that osteoporosis produces acute severe pain in the absence of a fracture. Spine pain can also be secondary to mechanical derangement of the spine such as kyphosis, especially when severe. Paraspinal muscle spasm, arthritis, nerve impingement or costal-iliac impingement syndrome, a painful rubbing of the rib cage against the iliac crest, can also be sources of pain (223). Signs and symptoms of vertebral fracture may be mimicked by neoplasm, herpes zoster, polymyalgia rheumatica, pancreatic disorders, and abdominal aortic aneurysm. It is important to investigate and treat the pain complaint promptly. If the patient experiences pain over prolonged periods, he or she may suffer consequences such as depression, sleep disturbance, and functional decline. The persistence of pain beyond 6 months at the site of a previous vertebral fracture may suggest causes other than original osteoporotic fracture; other etiologies of back pain in this group should be reconsidered, including progressed loss of height at original fracture site.

Plain film x-rays have poor sensitivity in diagnosis of osteoporotic sacral fractures (called *sacral insufficiency fractures*, or SIF) as well. There may be other associated fractures including rib fractures in addition to the sacral fracture in many cases. Therefore, a technetium-99 bone scan may be helpful in identifying such fractures, as well as their acuity.

The classic “H” or “Honda” sign seen on bone scan, representing combined bilateral vertical and horizontal sacral fractures, is present inconsistently and may vary from 15% to 68% (224). MRI demonstrating bone marrow edema as low-signal intensity on T1 weighted, high-signal intensity on T2 weighted images and the T2 weighted STIR images are particularly sensitive (225). However, CT is regarded as the gold standard in diagnosing occult fractures.

The osteoporotic patient complaining of acute pain resulting from vertebral fracture should be managed initially with rest, immobilization of fracture site, and analgesic agents. Because vertebral fractures generally heal well, management is directed at pain control and providing adequate rest and immobilization of the fracture site (Table 39-14). The unwanted side effects associated with analgesic agents may complicate treatment. Common pharmacologic interventions for acute

**TABLE 39.14 Rehabilitation Management of Back Pain in Patients with Vertebral Fracture**

#### Acute back pain

- Limit bed rest during the day; encourage good sleep and nutrition habits.
- Recommend analgesics to facilitate optimal function; utilize opiates with caution.
- Consider transdermal medicines to limit sedation (i.e., lidocaine or NSAID patch).
- Prescribe medications for constipation if needed, if natural remedies fail.
- Consider back brace (i.e., CASH brace, or rigid TLSO if risk for cord compression).
- Monitor for signs of radiculopathy and spinal cord compression at site of fracture.
- Teach proper bed positioning and mobility techniques, and emphasize spine-neutral principles during transfers, ADLs, and exercise.
- Train caregivers to assist patients safely with minimal spine loading.
- Prescribe appropriate ambulation assistive device where needed.
- Coordinate physical therapy and occupational therapy services as appropriate.

#### Chronic back pain

- Improve posture, transfers, and gait pattern to limit vertebral compression forces.
- Consider postural support orthotic to decrease ligament stretch.
- Adjust analgesics, as pain warrants; establish opiate management contract with patient.
- Prescribe a sound, on-going therapeutic exercise program.
- Consider vertebroplasty if conservative measures fail to improve pain profile.
- Evaluate and treat psychological and social consequences: consider relaxation techniques, biofeedback, support groups and self-management skills training.

Adapted from Sinaki M. Musculoskeletal challenges of osteoporosis. *Aging*. 1998;10:249–262; Sinaki M. *Musculoskeletal Rehabilitation in Osteoporosis: Etiology, Diagnosis and Management*. 2nd ed. Philadelphia, PA: Lippincott-Raven; 1995.

fractures include narcotics such as codeine, but in some cases transdermal applications (diclofenac, lidocaine), or oral tramadol may suffice. Within 3 to 4 weeks, weaning trials with other analgesic agents such as acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs) should be attempted, in conjunction with other pain therapies. NSAIDs, however, must be used sparingly and with caution in the elderly. Primary pain management should incorporate rest, orthoses, and physical agents, with pharmacologic agents serving as adjunctive therapy. A program of progressive activity is indicated after brief initial bed rest. Because of mechanical forces translated into the spine with bed mobility and transfers, these movements are typically more painful than ambulation at the onset of rehabilitative phase post-fracture. The use of a sheepskin, egg crate, or gel flotation pad on the mattress frequently enhances patient comfort. A stool softener and laxative will help prevent straining with bowel movements. Use of a bedside commode may prove easier than a bed pan and requires less energy expenditure. Progressive transfer and ambulation training should be provided by the therapist, followed by a gentle progressive resistive exercise program for the limbs. Resistive exercises are unlikely to cause fracture in osteoporotic bones of the limbs, but can cause a new fracture or progression of acute compression fracture if resistive forces are translated into the spine. Slow introduction of isometric exercises for abdomen and back muscles is considered safe. Strict adherence to neutral spine positioning during exercise is recommended.

A fracture of the spine can result in 3-5 times increased risk of further spine fracture, and a 1.2 to 1.9 increased death rate (226). Clusters of vertebral fractures may occur in patients age 50 and older, in rapid progression. The cause of this most aggressive form of osteoporosis is unclear, but may be associated with an accelerated trabecular bone loss soon after menopause, malnutrition, immobility, and in some cases in adjacent vertebrae to previous sites of vertebroplasty (see below). After a number of fracture events in the spine, the collapsed and/or anteriorly wedged vertebrae may lead to deformity of the back, with subsequent kyphosis, loss of height, and chronic pain in the area of the thoracolumbar junction, secondary to mechanical deformity and paraspinal muscle spasm. This chronic back pain is typically of lesser intensity than the pain associated with the acute fracture event; it radiates laterally, is associated with exertion, and is relieved to a certain extent with rest. In addition, with progressive spinal deformity and height loss, an abdominal protuberance and resultant gastrointestinal discomfort (bloating and constipation) may occur, as well as some degree of pulmonary insufficiency secondary to thoracic cage deformity. In patients with multiple fractures, and severe spinal kyphosis, costal-iliac impingement syndrome may result.

Although chronic back pain is a common complaint of the elderly, the extent to which osteoporosis contributes to this pain is questionable. In a study involving 242 women 55 years of age, 30% had complaints of back pain, but there was no relationship between this pain and spinal curvature. In a group of older women (60 to 79 years of age), back pain affected a similar proportion (30%) but was twice as likely to occur

in women with kyphosis or a loss in height exceeding 4 cm (227). There is not an absolute relationship, therefore, between osteoporosis and kyphosis. It is recognized that kyphosis may be secondary to chronic poor posture and age-related changes in muscles, ligaments, and intervertebral discs. Seventy percent of women over 60 years of age may demonstrate kyphosis without evidence of vertebral deformity. With aging, there is a progression of kyphosis (228), but back pain does not appear to be associated with the kyphosis unless vertebral deformity is such that there is a reduction in the height of the vertebral body greater than 4 SDs from normal (227).

Investigations into causes of back pain using bone scintigraphy showed a high incidence of facet joint disease in osteoporotic women with previous vertebral fracture, most prominently at the level of the vertebral collapse. Smaller lesions were commonly found in the facets above and below this level. Back pain with neurologic symptoms in the lower extremities may occur when vertebral fracture results in retropulsed fragments, or with associated foraminal narrowing, causing nerve impingement and radicular symptoms (229).

The pain of costal-iliac impingement syndrome is particularly difficult to treat. It is typically localized to the site of actual mechanical irritation, but can refer to the lower back and into the leg. Lateral bending and rotation can elicit this pain. Diagnosis is made by provocation of pain when palpating the lower ribs and the iliac crest contact site, and with lateral bending and rotation of spine. Injection of lidocaine into the margin of the iliac crest and lower ribs can be both diagnostic and therapeutic. Postural training, strengthening of abdominal and lumbar musculature, and the use of a wide, soft belt or CASH (cruciate anterior sternal hyperextension) brace have been reported as beneficial in relieving symptoms by lifting the ribs to avoid contact with the iliac crest. Concomitant trial with transdermal pain medications such as diclofenac or lidocaine should be considered, but narcotic medications may be needed. In severe cases, resection of the lower ribs has been beneficial (230).

In summary, the management of chronic back pain associated with osteoporotic vertebral fracture should include a program of strengthening paravertebral, abdominal, and gluteal muscles and safe programs to improve balance, flexibility, and posture. Relief of stress on the spine through use of proper body mechanics is encouraged. In severe cases, an orthosis can be of benefit. An assessment of ADLs may lead to the use of other techniques and devices that can help the patient avoid situations that aggravate pain. The strategic placement of a pillow or towel roll behind the back frequently increases sitting tolerance in patients with kyphosis. Physical agents such as heat, ice, transcutaneous electrical nerve stimulation, and acupuncture can be of benefit. Hypnosis, behavioral modification, biofeedback, and counseling have also been of benefit in the treatment of chronic pain.

### Back Supports and Bracing

The degree and types of skeletal pain and disability among patients with osteoporosis present a complicated challenge

to provide adequate mechanical support for the spine (231). When many solutions are available to answer a given problem, it usually indicates that there is no single good solution. Such is the case with mechanical supports for the osteoporotic spine. These orthoses may be used for pain relief and stabilization of the spine in both acute fracture and long-term care, and to promote healing and improved function. In the long-term treatment of the osteoporotic spine, orthoses may prevent further fracture.

When prescribing a brace or corset, one must understand the biomechanics of the spine, the types and causes of vertebral fractures, and the principles of bracing, including indications and hazards of individual orthoses (232). It is important to understand the functions of the lower thoracic and upper lumbar spine, where most compression fractures occur. The articulation of the thoracic vertebrae with the ribs, as well as the overlapping of the spinous processes, significantly limits its mobility in flexion and extension; rotation is relatively free, however. The lumbar spine has limited lateral flexion and axial rotation secondary to the relatively vertical orientation of the facet joints, so flexion and extension account for the majority of its movement. One must also understand the kinematic function or “coupling” that occurs in the thoracolumbar spine (233). While considering these functions of the spine, it is important to remember that movements that cause loading of the vertebral bodies increase the risk of fracture if bone density cannot support the resulting increase in applied force. Hence, bracing to help prevent this additional loading of the vertebral bodies must restrict flexion, which loads the anterior column of vertebrae. Restriction of flexion is therefore one goal of bracing, in conjunction with decreased pain, increased function, and prevention of soft-tissue shortening which may contribute to deformity.

There are several commonly used orthoses to stabilize osteoporotic vertebral fractures: postural training supports (PTS)-a weighted kypho-orthosis, thoracolumbar support such as the CASH brace, lumbosacral corset, and thoracolumbosacral orthosis (TLSO). All orthoses work on the principle of a three-point force system. Generally, the more rigid orthoses are used for acute thoracolumbar fractures, whereas the non-rigid orthoses such as the PTS and lumbosacral corset are used more commonly in the management of stable fractures and painful conditions. All orthoses described may not adequately prevent gravity-related axial compression, which may ultimately result in new fracture. Chronic use of spinal orthotics is generally discouraged because of the increased likelihood of weakening or atrophy of the trunk muscles, and reduced spinal mobility. Weakness of the supporting musculature may in time predispose to increased risk of vertebral fracture.

The PTS has been described as an inexpensive, unobtrusive device that promotes improvement in posture and decreases back pain by producing a force posteriorly below the inferior angles of the scapulae or by acting as a proprioceptive reinforcement (234). A TLSO such as the rigid clamshell brace is a long spinal orthosis that provides virtual fixation from the pelvis through the shoulders, and is commonly prescribed when vertebral fracture results in retropulsed fragments or severe spinal

stenosis that could compromise the spinal cord. Also, the lumbosacral region of the spine is one of the most difficult areas of the body to immobilize, requiring more than a simple lumbosacral orthosis after retropulsion has occurred. Although the TLSO affords the greatest immobility, it is cumbersome and hot, and noncompliance with wearing schedule is very common. When neurologic compromise is not an imminent risk, a semi-rigid TLSO such as SpinoMed or CASH brace is often used after vertebral fracture. Custom-fitted rigid TLSOs are also more expensive than the PTS and CASH brace.

The inexpensive abdominal corset has also been used to decrease pain, and increase function after an acutely painful vertebral fracture; it restricts movement via both mechanical and sensory feedback. This orthosis may also generate heat, pressure, or a massage-like effect that may be soothing for muscles in spasm. The use of corsets may also relieve pain by increasing hydrostatic support of the spine through increased intra-abdominal pressure, thereby placing an anteriorly directed force on the vertebral bodies. Again, this device can be hot, but it is not as bulky as a TLSO or CASH brace, can be worn under clothing, and has a higher compliance rate in patients with uncomplicated lumbar fracture.

Kaplan et al. conducted a pilot study to compare the effects of back supports on back strength in women age 40 and older with diagnosis of osteopenia or osteoporosis, who were randomly assigned to one of three groups: postural exercises (PE) alone, PE and conventional thoracolumbar support (CTLS), or PE and PTS. Compliance was poor among those who wore the TLS. The PTS and PE groups increased back strength significantly, implying that the more rigid CTLS inhibited strengthening of this area—a known complication of rigid bracing across any joint (235). Lynn and Sinaki found that kyphotic, osteoporotic patients had more postural sway and greater reliance on their hips to provide balance than did those with normal posture, who based balancing strategies in their ankles (236). Subsequently, they demonstrated that use of the PTS in these patients improved balance and decreased pain with only 1 month of PTS even in the absence of strong back muscles (237). The weighted PTS is thought to reduce pain by encouraging correct gravitational alignment and reduce strain to compensating muscles. In combination with back extensor muscle-strengthening exercises, the weighted PTS can contribute to the management of kyphotic pain.

In summary, rigid TLSO bracing is typically prescribed after vertebral compression fracture with retropulsed fragments and associated risk of neurologic impairment; noncompliance with wear is common, and associated risks must be discussed with patients. Other supports such as a non-rigid TLSO brace simple or a lumbosacral corset are better tolerated, and can be valuable after uncomplicated osteoporotic fracture. They reduce pain and facilitate early recovery of functional mobility and ADL function. The PTS can be useful in improving chronic pain and balance deficits in patients with kyphosis, but is not typically used after vertebral fracture. All spinal orthotics are thought to diminish excessive loading of the vertebral bodies, but chronic use is

not encouraged, so as to promote strengthening of intrinsic back muscles to support the skeleton.

### Vertebroplasty and Kyphoplasty

Vertebroplasty and its derivative kyphoplasty are spinal procedures first introduced in 1984, and 1998, respectively, in which a radio-opaque bone cement, polymethylmethacrylate, is injected into vertebral fractures with an 8-13 gauge bone needle under fluoroscopy or CT guidance. Figure 39-5 shows the outcome of injection, in a L4 compression fracture after vertebroplasty. Kyphoplasty requires slightly more time, as space for cement is created first by inserting an inflatable balloon tamp prior to injection. The procedure can be in-patient

or out-patient, in part dependent on medical status of the patient at time of procedure. These procedures are thought to stabilize the anterior column and any endplate fractures of the compressed vertebrae, in order to restore vertebral height, spinal alignment, and function to the greatest degree possible (238). There is growing evidence for efficacy in relieving unremitting pain from osteoporotic or pathologic vertebral compression fractures—up to 80% to 90% (239–243). However, well-controlled studies comparing these two procedures, or comparing either procedure with populations not receiving these interventions, are not yet available.

Although 700,000 vertebral compression fractures occur in the United States annually, one must clearly establish

**FIGURE 39-5.** Plain radiographs, L4 compression fracture: (A) Before vertebroplasty, (B) during vertebroplasty, and (C) after vertebroplasty. Courtesy, Veteran's Administration Central California HealthCare System, UCSF-Fresno.

by thorough history, physical examination, and correlative radiologic study that the compression fracture site in question is indeed the locus of debilitating pain. This is especially important because the typical age group of patients that develop osteoporotic vertebral fractures is also prone to degenerative joint disease of the spine, and consequent back pain. Although the thoracolumbar vertebrae are most likely sites for intervention, vertebral augmentation can also be performed at the cervical spine. An evolving intervention, sacroplasty, attempts to replicate the success of vertebral augmentation procedures for SIF (244).

Absolute contraindications for these procedures include uncorrected coagulopathy, preexisting systemic or spine infection, and on-going neurologic deficits secondary to the fracture site. Reported complications include extravasation of cement, bleeding, infection and neural injury, fractures, cement embolism, and predisposition to subsequent vertebral fractures at fragile adjacent vertebrae (12% to 52%) (245). There have been no comprehensive study reviews to date that have clarified this latter issue. Similarly, research is needed to evaluate whether the addition of back ergonomics and other post-compression fracture rehabilitation protocols such as postural and mobility training and back ergonomics 8 would improve functional outcomes with these procedures. Treating traumatic fractures in young persons with normal bone density is not considered appropriate with either technique (246).

A multidisciplinary team approach is beneficial to ensuring maintenance of function in this population. Nonpharmacologic interventions should be preferentially used to manage chronic back pain. This program should be supplemented by encouraging adjustments in lifestyle, medication use, physical agents, orthoses, and other therapies considered useful for chronic pain. These interventions are used only after ruling out other causes of back pain in the elderly, and after assessing the degree to which depression is contributing to the symptoms.

### Hip Fracture

Hip fractures may be divided into three categories according to the anatomic area in which they occur. Intracapsular fractures (femoral neck fractures) are located distal to the femoral head but proximal to the greater and lesser trochanters. These fractures frequently disrupt the blood supply to the femoral head and are therefore associated with nonunion and osteonecrosis of the femoral head, and typically require hemiarthroplasty for stabilization of the joint (247). Fractures occurring between the greater and the lesser trochanter are not associated with the complications seen in the intracapsular region. However, they are associated with malunion and shortening of the leg as a result of osteoporotic bone and the deforming forces exerted on this area of the proximal femur. Intertrochanteric and femoral neck fractures occur with equal frequency and together account for 90% of hip fractures. Subtrochanteric fractures occur just below the lesser trochanter and are responsible for only 5% to 10% of all hip fractures. Because 90% of peripheral osteoporotic fractures result from a fall, radiographs should also exclude fracture of the pubic ramus, acetabulum, and greater trochanter. Pain in this area after fall can also be associated with

trochanteric bursitis and sacroiliac dysfunction. In all patients, the goal of treatment is to return the patient, pain-free, to maximum level of mobility as soon as possible, address fall risks, and implement appropriate screening and treatment for underlying bone disease.

Rehabilitation begins on the first day after surgery with a progressive ambulation program. Special precautions to prevent deep venous thrombosis with anticoagulant medication such as enoxaparin or coumadin, and early mobilization are routine. Most patients begin walking on the first or second post-operative day, with weight-bearing status established by the orthopedic surgeon. When long-term stability of the surgical fixation is in question, weight-bearing status is decreased to minimize the possibility of hardware failure. Duke and Keating showed that mobility on day 2 following surgery was a significant predictor of independence at 2 weeks; independent mobility was defined as the ability to walk at least 15 meters with a walker and transfer to and from bed independently (248).

In a study involving a large patient population aged 65 years or older, Cree et al. found that almost all patients with cognitive impairment who had sustained a hip fracture were functionally dependent 3 months after the fracture and had acquired a new disability in transfers between chair and bed (249). Most of those who functioned independently prior to fracture functioned independently afterward, with post-fracture assistance most often needed in bathing and dressing. In those patients who were considered to be of high mental status, post-fracture dependence correlated with advanced age, a greater number of comorbidities, hip pain, previous employment in a high prestige occupation, and poorer self-related health (250). Magaziner et al. found little change in the areas of greatest disability in the respective 12- and 24-month follow-ups to hip fracture in previously independent patients: climbing five stairs (90% and 91%), toilet transfers (66% and 63%), and tub and shower transfers (83% at both intervals) (251).

The proportion of patients discharged to home after hip fracture ranges from 40% to 90%, although many patients remain institutionalized (252,253). Factors associated with permanent institutionalization are assistance with ADLs, age greater than 80 years, lack of involvement of family members, incontinence, and insufficient physical therapy at a skilled nursing facility (252). In a hospital-based comprehensive rehabilitation unit, more than 90% of these patients are discharged home. Although this high percentage has clearly been influenced by the selection process, the scope and intensity of rehabilitation services and the ability to manage acute exacerbation of comorbidities in close geographic relationship with an acute medical-surgical hospital may promote higher function. Discharge home is positively associated with presence of another person in the home, ability to walk independently before the fracture, ability to perform ADLs (252,253), absence of preexisting dementia, younger age, and preexisting social network (254).

The risk of death after a hip fracture is increased by a factor of 2.8 within the first 3 months after fracture, and is more likely in those in poor health (255), with mortality rate after

1 year approximately 20% in the NHANES I study. In fact, analysis of NHANES I data showed that with each SD decrease in bone density (e.g., each T-score decrease of -1.0), mortality increased by 10% to 40% (256). Increased mortality with hip fracture is also associated with institutionalization, preexisting medical conditions, surgical intervention before stabilization of coexisting medical conditions, poorly controlled systemic disorders, and complications of surgery (257), increasing age and male gender (18) and black race in females (19).

These patients often require the care of a physiatrist, physical therapist, occupational therapist, nurses, and social workers (258,259). The benefits of this multidisciplinary approach have been documented as resulting in fewer transfers for acute emergencies, fewer post-operative complications, improved ambulation at the time of discharge, and fewer discharges to nursing homes (252–254). Recent trends in health care delivery have challenged resources and have made rehabilitation strategies difficult to implement. The emphasis on shortened hospital stays has had a negative effect on patients with hip fractures. The number of patients remaining in a nursing home after 1 year is now much higher than before the initiation of the prospective payment system (253). There are increased costs to insurers and to patients as a result of the acceleration of patients through a system of care that does not account for patients' individuality, degree of impairment or disability, existing comorbidities, and social resources. The largest cost to the patient is loss of independence as a direct result of denial of access to the proper scope and intensity of rehabilitative services.

### Wrist Fracture

Fractures of the wrist are the most common type of fractures in women less than 75 years of age. A prior wrist fracture doubles the risk of any future osteoporotic fracture in postmenopausal women and triples the risk for a second wrist fracture (260). These fractures increase in number after menopause, and although they usually occur in relatively healthy active women, they may be the first sign of an underlying problem such as low bone mass. The primary goal of treatment is return of pain-free normal function of the hand and wrist. Initial casting does not usually extend above the elbow. During the period of immobilization, usually 6 to 8 weeks, strength and flexibility should be maintained in the upper extremities. Active and passive range-of-motion exercises should be provided for the fingers and shoulder on the affected side, with close monitoring for signs and symptoms of median nerve impingement (carpal tunnel syndrome) secondary to cast impingement with post-fracture edema. These exercises should be continued after cast removal, with wrist, forearm, and elbow range of motion and exercise added. At that time, a local wrist splint may be used to support and protect the wrist. As a result of the wrist fracture, particularly on the dominant side, the patient may require assistance with ADLs such as getting dressed, combing hair, and brushing teeth.

MacDermid et al. reported the rate of improvement to normal pain-free function after distal radius fractures to be

highest in the first 6 months after the fracture, with gains generally leveling off during the next 6 months (261). Of note, even with well-healed fractures, pain may persist because of ligament or triangular fibrocartilage complex (TFCC) injuries, which are common and can often be missed in the initial work-up for a wrist fracture (262–264).

### FEMALE ATHLETE TRIAD

With the advent of Title IX in the early 1970s, high school age girls' participation in organized sports has increased 1000% (265). With increased energy expenditures as training becomes more intensive, caloric intake must be increased accordingly. Carbohydrates should compose approximately 60% of daily caloric intake by American Dietetic Association guidelines, with fats comprising 25% to 30%, and proteins 15%. Carbohydrates are therefore the primary source of muscle energy, and adequate total caloric intake prevents sacrifice of body fat and proteins. Although vitamins, minerals, and water also are essential for health, they do not provide energy.

With increased energy expenditures as training becomes more intensive, caloric intake must be increased accordingly. Not increasing caloric intake after increased exercise can precipitate weight loss, and sacrifice of adipose tissue for training needs. This can deplete estrogen stores sufficiently to cause amenorrhea in female athletes. This increases the risk of osteoporosis and stress fractures, especially in conjunction with eating disorders, such as is seen in FAT. Eating disorders have been reported as high as 62% in college female athletes, and are becoming more common in adolescents. Although secondary amenorrhea in the general population is approximately 5%, it can increase to 10% to 20% in college athletes and 50% in elite athletes (266). Delayed menarche or absent menses for more than 3 months, particularly during times of increased training, should prompt clinical evaluation, including history of intentional weight loss strategies (i.e., diuretics, bulimia or anorexia, laxatives, avoidance of "fear foods"), distorted body image, and refractory pain sites. Evaluation with nutritionist is recommended, with psychologist or psychiatrist if warranted, if eating disorder is suspected. In-patient treatment should be considered in patients refractory to treatment efforts. Monitoring for bulimia in light- and middle-weight category male wrestlers, especially prior to competition, is also needed. Although these athletes are not as likely to fracture, there is concern they will be at increased risk of fracture as they age, if bulimic behavior coexists with the bone formation phase of adolescence.

In addition to basic osteoporosis laboratory tests (see Table 39-8) hormonal evaluation (pregnancy test, Thyroid Stimulating Hormone (TSH), Follicular Stimulating Hormone (FSH), and prolactin) is required in these patients, including estradiol level checked between days 2 and 4 of expected menstrual cycle. Any deficiencies must be addressed clinically. During childhood and adolescence, it is normal to see ongoing bone growth at bone metaphyses by plain radiographs,

and corresponding elevation of bone turnover markers such as urine or serum NTX. This precludes their use to monitor treatment efficacy in this population. Although IGF-I and DHEAS are useful markers in FAT research, at present they cannot be used clinically in young patients at high risk, such as is seen in anorexia nervosa or cerebral palsy (267). Similarly, applicability of DXA T-scores for bone mass assessment is not recommended in pediatric populations; Z-score monitoring is under investigation and will likely prove useful clinically in the future.

With FAT, stress fractures usually occur at the tibia or hip. If plain radiographs are negative, MRI is needed, as it can differentiate best between fracture and soft-tissue injury, such as anterior tibialis muscle tear. Calcium and vitamin D supplementation, oral contraceptive therapy, and a minimum 6 weeks non-weight bearing in the fractured extremity is the standard of care in this population. Bed rest in hospitalized anorexic patients should be used with caution, so as to limit further bone loss. Resistive exercise regimens for the other limbs are recommended during the bone-healing phase, provided the patient follows strict nutritional guidelines for caloric intake for energy expenditures. Return to regular exercise and competitive sports requires close monitoring of caloric intake and weight, with nutritional and mental health counseling if needed. Although oral contraceptives can be used to regulate menses and improve bone mass in these patients, irreversible osteoporosis is common.

In summary, physical medicine and rehabilitation expertise can be of great value in the management of patients with osteoporosis and is currently underused. These strategies are used to reduce disability resulting from impairments in bone mass and structure, muscle strength, and coordination. With a timely, focused, coordinated plan of care, preventively or after fracture, disability can be minimized.

## ELECTRONIC MEDICAL RECORD SYSTEMS COORDINATION

More comprehensive osteoporosis screening and treatment will require expanded utilization of existing medical and electronic resources to improve communication between physicians and their patients. Multiple studies in Europe and America have shown that electronic medical record utilization, in strict compliance with patient privacy guidelines, has had good-to-excellent results in improving management of low bone mass (268–271). The best results to date in the United States have been in private health maintenance organizations. Newman et al. reported in 2003 that EMR targeting within a small, rural Pennsylvania Health Maintenance Organization of at-risk women 55 and older for DXA screening and osteoporosis treatment resulted in reduced hip fractures over a 5-year period in women 65 and older, with \$1.5 million savings per annum over baseline in direct costs of care (272). Later EMR targeting of those patients who required chronic glucocorticoid medication resulted in 96% compliance with calcium,

vitamin D, and prescription medication where indicated, significant improvement in bone density at hip and spine, and improved exercise frequency and vitamin D levels (273). A comprehensive screening, education and treatment program in California for patients age 65 or older at risk for osteoporosis reduced hip fractures by 37%, saving a larger private health plan approximately \$30 million over 5 years (274). Studies have also demonstrated the benefit of a nurse coordinator or manager to improve appropriate treatment and decrease hip fractures (275) and provide patient education (276).

## SUMMARY

Osteoporosis is a disease that is defined as both an intermediate outcome (BMD <2.5 SD from young adult baseline) and as a metabolic disease that can facilitate a fragility fracture of the spine or hip from a fall from a standing height. In this light, low BMD can be considered a precipitating factor for the latter, just as uncontrolled hypertension can lead to stroke. Research has shown that the negative outcomes of osteoporosis, like other disease entities, do respond to traditional public health strategies to improve clinical, radiologic, and laboratory screening and the success of expanding treatment options. Recent evidence-based research has better defined risks and treatment strategies for female and male patients of all ages, and specific ethnic groups in the last decade. Further research is needed to expand our knowledge of causes of secondary osteoporosis in males, and optimal screening and treatment strategies (277). Similarly, further investigation into the genetic basis for osteoporosis, optimal bone-building strategies for pediatric and adult populations, including persons with disability, and the role of exercise in preventing falls and optimizing BMD is needed.

The decision to screen for low BMD should be based on an individual's risk factors and on treatments being considered. It is important to ensure that adults receive up to 1,200 mg of calcium per day in diet and supplements, and 800 to 1,000 IU of vitamin D daily, provided there are no medical contraindications to this regimen. Protein intake is also critical, with supplementation, particularly after hip fracture, considered for those at risk. Education of patients regarding secondary causes of osteoporosis and lifestyle choices, such as smoking, and the need to engage responsibly with health care professionals in an active preventive and treatment program is critical to reducing the disabling consequences of this disease. Regular weight-bearing exercise, particularly those aimed at improved balance, can help prevent osteoporotic fractures through osteogenic effects and prevention of falls. Many medications, including bisphosphonates and hormone replacement therapy, have shown success in decreasing bone resorption, to reduce fracture risks for those with low BMD (osteopenia) and osteoporosis. Teriparatide, which induces bone formation, and denosumab, which slows resorption via inhibition of RANKL, also help to prevent progression of osteoporosis and fractures.

Physical medicine and rehabilitation strategies can be of value in the management of patients with osteoporosis, but are

currently underused. There is increasing evidence that expanding traditional rehabilitation interventions (i.e., pain management, posture and exercise programs, and fall reduction strategies such as proper footwear, and appropriate environmental adaptations) in combination with adjustment of medications contributing to polypharmacy—particularly sedatives, antidepressants, diuretics, and antihypertensive agents—can significantly reduce the risk of falling, which in turn reduces the incidence of all fractures. The benefits of assistive devices such as canes, walkers, and wheelchairs for those with disturbed balance or deficits in gait should also be emphasized as frailty develops with aging and disability. Interventions such as vertebroplasty are becoming more prevalent for stabilizing spine integrity after compression fracture, but require further controlled studies for long-term benefit and efficacy. Targeting persons with chronic disability, who are at increased risk of bone loss compared to their more mobile peers, is particularly needed.

By utilizing both medical and traditional rehabilitation strategies, physiatrists can play a unique role in the interdisciplinary model to optimize screening and treatment efforts within the medical community. The implementation and coordination of these efforts in all in-patient rehabilitation settings, particularly during the seminal post-fracture period, could prevent further fracture, and reduce disability resulting from impairments in bone mass and structure, muscle strength, and coordination. To advocate for our patients in order to increase the likelihood of independent community dwelling, and to improve the quality of life for those in extended care facilities who have double the risk of falls, is at the core of our mission as physiatrists.

# Rehabilitation of the Patient with Rheumatic Diseases

Arthritic diseases are having an increasing impact on public health (1). It is estimated that musculoskeletal disorders are the most frequent cause of disability in developed countries (2). Currently, 46 million people are affected by arthritis, and this number is predicted to rise to 67 million by 2030. These individuals often sustain impairments, functional losses, and disability. The annual cost in medical care and lost wages is \$128 billion (3). Twenty-first century physicians who care for these patients must be aware of current pharmacologic and rehabilitation strategies to control disease, limit impairment, preserve or enhance function, and reduce disability (1).

New trends have been developing in the management of inflammatory arthritis: (a) early use of disease-modifying antirheumatic drugs (DMARDs) in combination with reduction in disability (4), (b) a transition from passive patient involvement in treatment to self-efficacy, (c) a change from prescribing rest, to one of advocating relative rest and activity, (d) an increased use of rehabilitation early in the disease course, (e) a greater use of complementary and alternative therapies by patients and health care providers, and (f) an increased interest in which rehabilitation measures are available and are efficacious in achieving preventative and restorative goals for arthritis patients.

The specialty of rheumatology is dedicated to the understanding and control of disease activity. Physical Medicine and Rehabilitation has its roots in maintenance and restoration of function as well as prevention of dysfunction. This is achieved by having a keen knowledge of the impairments associated with the various rheumatic diseases (RDs) and the formulation of individualized treatment plans to maximize patient function by utilizing education, physical modalities and techniques, exercise, assistive and adaptive devices, energy conservation, joint protection, and vocational planning. The care of arthritis patients takes a multidisciplinary team effort. It is currently accepted that early diagnosis, medical treatment, and rehabilitation are preferable. Orthopedic interventions are often necessary and need to be appropriately timed.

This chapter addresses inflammatory diseases and their impact on the person as a whole, on specific joints, and on involved organ systems. Appropriate rehabilitation strategies are presented.

Inflammatory arthritis may involve a single joint or multiple joints, periarticular structures, and other organ systems. It may be an acute process that completely resolves (e.g., septic joint), or may be a chronic process (e.g., rheumatoid arthritis [RA]). Inflammatory arthritis may involve all the joint structures: synovium, cartilage, tendons, capsule, bone, and surrounding muscle. It is often part of a systemic RD (i.e., connective-tissue disease) such as RA, juvenile idiopathic arthritis (JIA) (formerly known as juvenile rheumatoid arthritis [JRA]), systemic lupus erythematosus (SLE), dermatomyositis/polymyositis (DM-PM), progressive systemic sclerosis (PSS), or mixed connective-tissue disease (MCTD). These diseases are usually chronic, remitting, and relapsing; are variable in their course; and affect multiple organ systems in addition to joints. They most often require long-term treatments with pharmacological agents, which may have a significant impact on appearance, sleep, psychological function, and reproductive ability. The physiatrist directing the rehabilitation team must take these issues into account when evaluating and devising a treatment plan.

This chapter emphasizes the importance of a good initial evaluation, early treatment intervention, and periodic reevaluation of the arthritis patient. It describes the rational and stage-specific manner in which rehabilitative treatments are applied to the problems of patients with RDs and the current scientific evidence, or in the absence thereof, the seasoned clinical judgment for their use. Equally important is to stress the critical need of engaging the patient in his or her own treatment (5).

## ARTHRITIC DISEASES

### Classification

The important determinants in classifying arthritis are whether the disorder is inflammatory versus noninflammatory, symmetric versus asymmetric, or accompanied by systemic and extra-articular manifestations (Fig. 40-1). A detailed history and physical examination, and appropriate laboratory and x-ray studies will often allow a specific diagnosis to be made. Clinical features that suggest inflammatory rather than noninflammatory disease include: acute painful onset, fever, erythema

**FIGURE 40-1.** Steps in the classification and diagnosis of RD.

of the skin over the joint or joints involved, warmth of the joint or joints, and tenderness that usually parallel the degree of inflammation. Laboratory and x-ray findings that suggest an inflammatory process include an increased peripheral

white blood cell count with left shift, an elevated erythrocyte sedimentation rate (ESR), a group II joint fluid (Table 40-1), and x-ray demonstration of soft-tissue swelling, periostitis, bony erosions, or uniform cartilage loss (Table 40-2).

**TABLE 40.1** Synovial Fluid Analysis

Fluid Group	Color	Clarity	Viscosity	Mucin Clot	Cells/mm <sup>3</sup>	Percentage of White Blood Cells That Are Polymorphonuclear Leukocytes
Normal	Pale yellow	Transparent	High	Good	<25%	<10%
Group 1 (noninflammatory)	Yellow or straw	Transparent	High	Good	<2,000	<25%
Group II (moderately inflammatory)	Yellow or straw	Transparent to opaque, slightly cloudy	Variably decreased	Fair to poor	3,000–50,000	>70%
Group III (highly inflammatory, septic)	Variable; yellow-gray, purulent	Opaque, cloudy	Low	Poor	50,000–100,000 (usually 100,000 or more)	>75%, usually close to 100%
Group IV (hemorrhagic)	Red	Opaque	High	Good	Up to normal count in blood	May be the same as normal blood

**TABLE 40.2 Radiographic Findings in RDs**

Disease	Anatomic Distribution	Types of Changes Seen
Rheumatoid arthritis	Symmetric: Most frequent: MCP, MTP, wrist, PIP Often: Knee, hip, ankle, shoulder, C-spine	Juxtaarticular OP, fusiform soft-tissue swelling marginal erosion, bony cysts Subluxation (swan-neck/Boutonniere/ulnar deviation) Late: bony eburnation, compressive erosions, surface resorption
Spondylarthropathies AS Reiter's PSA	Asymmetric: Most frequent: Sacroiliac joint, heel Vertebral column, hip, shoulder Knee, ankle MCP, PIP, DIP, MTP	Soft-tissue swelling, sausage fingers (i.e., Reiter's, PSA) New bone formation, fluffy periosteal bone, and syndesmophytes Enthesopathic ossification or erosion or both Bony ankylosis Severe—arthritis mutilans
Septic	Asymmetric: Knee, ankle, wrist, hip, small joints	Soft-tissue swelling—periarticular Joint space enlargement Periosteal elevation Late: bony destruction
Gout	Asymmetric: First MTP, small joint, knee, elbow > feet and hands	Soft-tissue swelling Soft-tissue speckled calcification, gouty tophi Erosion of bone with marginal overhangs
Pseudogout	Symmetric: Knee, wrist, hip>> Intervertebral discs, shoulder (glenoid labrum and acetabulum)	Chondrocalcinosis Subchondral cysts
SLE	Symmetric: Small joints of hands, feet, wrists  Articular osteonecrosis: Hip, knee, shoulder, ankle	Calcific deposits Subchondral lucency (i.e., crescent sign/osteonecrosis) Subchondral sclerosis Subchondral collapse and remodeling of bone/tuft resorption
PSS	Symmetric: Small joints of hands and feet	Late: joint space loss Acroosteolysis (i.e., bone resorption) Soft-tissue calcification Sausage digits
Juvenile chronic arthritis (JIA seronegative chronic RA, Still's disease)	Femoral condyle, humeral head, radial head, phalanges, MCP, MTP, femur, tibia, fibula, radius, C-spine	Epiphyseal enlargement, flattening and abnormal diaphyseal growth Osteopenia, OP, soft-tissue swelling Periostitis and apophyseal narrowing

AS, ankylosing spondylitis; RA, rheumatoid arthritis; OP, osteoporosis; PSA, psoriatic arthritis; PIP, proximal interphalangeal; Reiter's, Reiter's disease; MCP, metacarpal phalangeal; MTP, metatarsal phalangeal; JIA, juvenile idiopathic arthritis; PSS, progressive systemic sclerosis; DIP, distal interphalangeal joint; SLE, systemic lupus erythematosus; >, greater than; >>, greater than.

Inflammatory arthritis falls into four different groups and may be monoarticular or polyarticular (6,7):

1. Inflammatory connective-tissue disease (e.g., RA, JIA, SLE, PSS, DM-PM, MCTD, psoriatic arthritis [PSA])
2. Inflammatory crystal-induced disease (e.g., gout, pseudogout, basic calcium phosphate)
3. Inflammation induced by infectious agents (e.g., bacterial, viral, spirochete, tuberculous, and fungal arthritis)
4. Seronegative spondyloarthropathies (e.g., ankylosing spondylitis [AS], PSA, Reiter's syndrome [RS], inflammatory bowel disease [IBD]).

Noninflammatory arthritis may be classified as:

1. Degenerative, posttraumatic, or overuse (e.g., osteoarthritis [OA], posttraumatic aseptic necrosis [AN])

2. Inherited or metabolic (e.g., lipid storage disease, hemochromatosis, ochronosis, hypogammaglobulinemia, hemoglobinopathies).

Criteria for classification may be found in the Primer of the Rheumatic Diseases, 13th edition (8). A number of these diseases have systemic manifestations (Table 40-3), many of which should be addressed in addition to treatment of the arthritis itself. The physiatrist must be aware of the impact of a chronic, unpredictable illness on various life stages. For example, systemic disease may influence a young mother quite differently from a postmenopausal woman. In some diseases (e.g., RA, SLE, JIA, gout, AS, PSS, DM-PM), a number of set criteria delineated by the American College of Rheumatology (ACR) must be fulfilled before a definite or probable diagnosis can be made.

**TABLE 40.3 Systemic Manifestations of RDs**

System	Disease
Skin	Juvenile idiopathic arthritis
	Psoriatic arthritis
	Reiter's syndrome
	Colitic arthritis
	Sarcoid arthritis
	Septic arthritis (especially <i>Neisseria gonorrhoeae</i> and <i>meningitides</i> )

## Demographics

Many types of arthritis have a specific distribution in terms of age, gender, race, and geographic appearance. Severity of disease may vary with age and gender. Genetics and occupation may also be influencing factors. It is helpful to be familiar with those portions of the population that are more susceptible to certain diseases (Table 40-4) (9).

## Etiology and Pathophysiology

Because the designation RD includes such a broad spectrum of processes and syndromes, a classification system (see Fig. 40-1) that groups arthritides to some extent by etiology may be useful.

## Rheumatoid Arthritis

RA is the most common of the inflammatory arthropathies and is often difficult to diagnose in its early stages. The etiology of RA remains unknown, although much has been learned in the past two decades about the inflammatory process, its relationship to the immune system, and molecular genetic regulation (10). Of the two hypotheses in vogue, one suggests that RA is an autoimmune disorder; the other proposes that specific external agents initiate the response, which then is perpetuated or amplified by the immune host response. Data in support of the first hypothesis are derived from the fact that antibodies against autologous immunoglobulin G are present in many patients with RA, which may represent a primary abnormality in the regulation of cells that control immunoglobulin synthesis. Rheumatoid factor (RF) has been associated with more severe disease and almost exclusively with extra-articular disease. This primary defect may alter the control mechanisms, so that stimulation and control of these events are unbalanced and the response to endogenous immune products goes awry.

A more likely explanation for the etiology of RA is that specific external agents initiate an inflammatory response, and in the susceptible host, the inflammation leads to continual disease activity. Infectious agents can cause synovitis. Some replicate in the joint space (e.g., *Mycobacterium*, *Staphylococcus*), and some enter the joint space and cause synovitis initiating a local immune response (e.g., rubella, spirochete). Lyme disease is an example of a spirochete-initiated disease that can be associated with chronic arthritis. Another type of arthritis follows gastrointestinal (GI) disease (e.g., *Shigella*, *Salmonella*, *Yersinia*). No organism is recovered from the joint, although a reactive arthritis occurs, and the inflammatory process is initiated by a remote infection. All efforts to associate an infectious agent with RA have failed, despite sophisticated electron microscopy and molecular biology techniques. Exposure to cigarette smoke is an additional environmental factor believed to play a role in increasing the risk for development of RA (11,12). Several components need to be acknowledged in the understanding of this process: an inciting agent, most likely exogenous and possibly a wide range of antigens; a genetic susceptibility; and an abnormality in the host immune response.

The mechanism of tissue injury in RA has been demonstrated to include the following components of the immune system and its associated mediators of inflammation. In the affected host, a stimulus initiates an inflammatory response directed against self or nonself, which sets into motion complement, leukocyte phagocytosis, lysosomal enzyme release, and several small mediators that may initiate clotting and fibrolysis. In the joint, the local reactions are helper T-cell (in particular CD4 T cells) mediators that are attracted to macrophages and dendritic cells. Antibody synthesis is initiated, thus perpetuating the immunologic activities already begun. Cytokines play a key role in the perpetuation of synovial inflammation. Many have been found in the RA synovium (11,13). These cytokines are targets for clinical drug trial interventions. Some of the joint mononuclear cells can produce proteinases, prostaglandins (PGs), and other small mediators of inflammation.

**TABLE 40.4** Epidemiology of Inflammatory Arthritis

Disease	Incidence (per 100,000)	Prevalence (per 1,000)	Peak Visit (years)	Gender	Frequency by Race
RA	32.7	10 (1%)	25–50	2.5:1 female	Higher in whites and Native Americans (Pima Indians)
JIA	3.5–13.9	1–2	1–3	2:1 female	Lower in African Americans, Asian and Japanese
SLE	2–8	0.5–1	15–40	9:1 female	Three times higher in blacks, Chinese; increased in Haida, North American Indian
AS	7.3	1.5	25–44	3:1 male	Higher in Central European
PM	1.0	0.1		2.5:1 female	Three times higher in black females
PSS	0.9–1.9	0.29	30–50	4:1 female	Increased in Southern U.S. higher among African Americans
Gout	>120	27.5	45–65	10:1 male	African Americans. Asian-Pacific Islanders

RA, rheumatoid arthritis; AS, ankylosing spondylitis; JIA, juvenile idiopathic arthritis; PM, polymyositis; SLE, systemic lupus erythematosus; PSS, progressive systemic sclerosis.

Tissue inflammation causes the synovial membrane to become hyperplastic and neoangiogenesis occur, with the production of chemokines that increase the influx of more inflammatory cells. Synovial fluid enzymes directly affect the articular cartilage. Bone erosions develop when the synovial membrane has invaded the cartilage. Production of metalloproteinases, fibroblasts, and monocytic phagocytes produced by the synovium is controlled by cytokines (IL<sub>1</sub>, TNF<sub>2</sub>, and TGF- $\beta$ ). These cytokines influence chondrocytes to produce less collagen and proteoglycan, and increase collagenase synthesis, which degrades type II collagen (14). As the high-intensity inflammation subsides in the joint, repair takes place, often with the proliferation of fibroblasts and scar tissue. Although it is unclear what triggers this, once the process is in place it often continues for a longer period than would be expected to successfully clear the antigen. Hence, the host immunoregulatory system, which is genetically controlled, must be abnormal. In addition, people with RA often have systemic manifestations with other organ damage mediated by immunologic processes. An example of immune abnormality in RA is the inappropriate reduction in thymic function (15).

### Systemic Lupus Erythematosus

SLE is a multisystemic disease that is associated with abnormalities of immune regulation and immune complex-mediated tissue injury. It has been called a classic autoimmune disease, as a result of an abundance of autoantibodies generated against cytoplasmic and nuclear cellular components. The hallmark of these is generation of IgG antibodies to double stranded DNA. The etiology of SLE is obscure, but viral inclusion bodies have been implicated because of electron microscopic observations made in lymphocytes and vessel walls. Virus has never been isolated in patients with SLE; even those diseases with documented infectious etiologies are often multifactorial. Family members with SLE are more likely to have immunologic abnormalities than are controls. Hormonal influences are important in the expression of SLE, and women in the child-bearing years appear to be at greater risk. Women taking

progestation-based oral contraceptives are at higher risk than those taking estrogen-based oral contraceptives. The pathogenesis of SLE depends on abnormalities in humoral and cellular immunity. Lymphopenia is common and is inversely related to disease activity. B-lymphocytes are normal in number but are hyperactive. T-lymphocytes are often decreased, most markedly in the T-suppressor lymphocyte subpopulation. Natural killer cell activity is diminished, but there are an increased number of lymphocytotoxic antibodies (16).

### Progressive Systemic Sclerosis

PSS is a progressive disorder in which microvascular obliterative lesions in multiple organs terminate in fibrosis and atrophy. The hallmark of this disease is induration of the skin. Patients with PSS have capillary abnormalities and small artery lesions that appear late with organ involvement. The pathogenesis of organ involvement is most likely due to injury to the endothelial cell lining of vessels. Disturbing the lining activates the clotting system, with the release of vasoactive peptides. These factors stimulate smooth muscle cells to migrate in, proliferate, and deposit connective tissue, which results in the proliferative vascular lesions of PSS. The etiologic agent is obscure, and no strong hypotheses exist as to its nature (17).

### Idiopathic Inflammatory Myopathies

Polymyositis (PM), dermatomyositis (DM), and inclusion body myositis (IBM) are part of a heterogeneous group of diseases characterized by inflammation of muscle and skin, often associated with profound weakness of all striated muscle, including the heart, and elevated levels of skeletal muscle enzymes. There are six types, each of which may have a different etiology (18);

- Group 1: Primary idiopathic PM
- Group 2: Primary idiopathic DM
- Group 3: DM-PM associated with neoplasia
- Group 4: DM-PM associated with vasculitis (juvenile dermatomyositis [JDM])
- Group 5: DM-PM associated with collagen vascular disease
- Group 6: IBM

Two leading hypotheses may explain the etiology of DM-PM: viral infection and abnormal recognition of self. Immunoglobulins have been demonstrated in vessel walls, especially in intramuscular blood vessels, suggesting that these deposits are immune complexes to muscle. These deposits are seen in a variety of muscle-wasting conditions and may be nonspecific. Cellular immunity is abnormal with DM-PM, as demonstrated by myotoxic activity of the lymphocytes in patients with DM-PM. Skeletal muscle antigens cause lymphocytes of patients with DM-PM to proliferate, suggesting that the lymphocytes are inappropriately responding to these antigens.

### Crystal-Induced Synovitis

Crystal-induced synovitis can be caused by uric acid, calcium pyrophosphate, hydroxyapatite, and cholesterol crystals. Best understood is gout, a familial disorder in which there is a deficiency of hypoxanthine-guanine phosphotransferase, resulting in an overproduction of uric acid. Hyperuricemia results, and as the concentration of urate in the blood increases, monosodium urate crystals precipitate in the tissue. It has been shown that injecting urate crystals subcutaneously will cause tophus formation, and when urate is injected into joints, gouty attacks will ensue. Other factors involved in the pathogenesis of the gouty attack include elevated temperature, which increases the joint urate concentration, lowered pH, trauma, and aging (19).

Pseudogout, or calcium pyrophosphate dihydrate deposition (CPPD), can be hereditary or sporadic. The etiologic agent is the calcium pyrophosphate crystal, which is formed secondary to a disorder of local pyrophosphate metabolism. The crystals adhere to leukocytes, and often immunoglobulin is absorbed, which stimulates phagocytosis and the perpetuation of inflammatory arthritis. These calcium-containing crystals get deposited in the pericellular matrix of cartilage and can present as chondrocalcinosis (20).

### Spondyloarthropathies

Spondyloarthropathies are polyarticular disorders that primarily involve the sacroiliac joints, vertebral column and, to a lesser extent, larger, peripheral joints (shoulder and hip). There may also be an association with a variety of extraspinal lesions including the eyes, the GI track, cardiovascular system, lungs, kidneys, and skin. These arthritides share a number of additional features, including mucocutaneous lesions, sacroiliitis, heel pain, and the B27 antigen. Antecedent GI infection, caused by *Salmonella*, *Shigella*, and *Yersinia*, has stimulated interest that these diseases may be caused by a gram-negative organism (21). The most convincing data in support of this came from the well-documented *Shigella* epidemic, in which RS occurred in 344 of 150,000 infected persons in one study (22) and in nine of 602 in another study. No case occurred in anyone who was not infected. Arthritis with some additional features of RS has followed *Salmonella* and *Yersinia* infections. In PSA and AS, the data are less convincing, but evidence has linked the development of guttate psoriasis and streptococcal

infection. The presence of B27 antigen appears to be the crucial link in the expression of the disease. Antecedent urethritis has also been associated with acute arthritis, and chlamydia is the organism most frequently identified.

The pathology occurs at the entheses (insertion of tendon to bone). The axial spine may fuse, but if the peripheral joints are involved, there is erosion and often bony reaction and periosteal new bone growth. Usually, there is no periarthritic osteoporosis (OP). In summary, the etiology of spondyloarthropathies is most likely an infective agent, possibly Gram-negative bacteria, that interacts with a susceptible gene host: B27 in AS and RS, and perhaps B27, B38, and C6 in PSA (23).

### Infectious Arthritis

A wide variety of infectious agents can cause arthritis secondary to the infection itself or as a consequence of the host's immunologic response. The organisms can be viral (e.g., hepatitis, rubella, mumps, herpes); bacterial (e.g., Gram-positive *Staphylococcus*, *Streptococcus*, and *Pneumococcus*; Gram-negative *Neisseria* and *Hemophilus influenzae*; *Pseudomonas*, mycobacterium tuberculosis), spirochete (Lyme disease), or fungal. Recently, interest has developed in the role of hepatitis C and the development of an RA-like arthritis (24).

## PATIENT EVALUATION

A detailed history, physical examination, laboratory, and x-ray findings are essential to the proper diagnosis and management of RDs. Many schemes have been developed in an attempt to construct an organized approach to the classification of RDs, including algorithms that sort signs and symptoms around the presence or absence of inflammation, symmetry, and number of involved joints. However, these categories are not very helpful in sorting out the underlying pathophysiologic processes that need therapeutic intervention. A practical approach is suggested by James Fries, in which eight specific types of musculoskeletal pathology are distinguished (25). Patients can have more than one type of pathology; for example, enthesopathy and synovitis present in patients with PSA (Table 40-5). A more recent approach to patient evaluation, incorporating the World Health Organization (WHO) biopsychosocial model for patient evaluation, may be useful (26). Patient assessment from this approach will seek out not only the primary etiology and how the disease process affects the organ or system but also the associated effects on the patient and his or her interactions with the environment.

### History and Examination

A detailed description of the symptom onset, prodromal symptoms, setting, pattern, and sequence will greatly aid in establishing a differential diagnosis. Exacerbating or remitting factors, functional impairments, and therapeutic effects should also be documented (27).

**TABLE 40.5** Evaluation of RDs

Pathology	Examples	Laboratory Tests	Other Organs Involved
Synovitis	Rheumatoid arthritis Psoriatic arthritis/Reiter's syndrome	Latex, x-rays x-rays	Lung, heart, skin nodules Skin
Enthesopathy	Ankylosing spondylitis Psoriatic arthritis/Reiter's syndrome	HLA-B27, sacroiliac joint, X-rays, MRI	Heart Skin, mucous membrane
Crystal arthritis	Gout Pseudogout	Serum uric acid, joint fluid	Skin, kidney
Joint infection	Bacterial Viral Fungal	Joint culture, joint fluid	Vaginal infection Bacteremia Hepatitis
Joint effusion	Trauma Reactive arthritis Metabolic/endocrine disorders	Joint fluid	Thyroid livers Any organ
Vasculitis	Scleroderma DM-PM SLE Polymyalgia	Muscle biopsy EMG Antinuclear antibody ESR CRP	Heart
Tissue conditions			
Local	Tendinitis		
Generalized	Fibrositis		

DM-PM, dermatomyositis-polymyositis; CRP, C-reactive protein; EMG, electromyography; SLE, systemic lupus erythematosus; MRI, magnetic resonance imaging.

*Pain* is the most likely presenting symptom. Although often difficult to define, anatomic location and symmetry, character (e.g., burning, aching), and severity or intensity (graded by a numeric ten-point scale) should be included.

*Stiffness* may be seen as well. This term should be well-defined and its meaning to the patient should be understood. Timing, duration, and location of stiffness should be noted. For example, in the diagnostic criteria of RA, morning stiffness lasting at least 1 hour is included. This stiffness also known as a “gelling phenomenon” can be noted after sitting or maintaining a fixed position for some period of time which in some cases may be as short as 20 to 30 minutes but typically greater than 1 hour.

*Range-of-motion (ROM) limitations* may accompany complaints of stiffness. These symptoms in the rheumatologic population are usually not transient and should not be confused with gelling or stiffness. Noting symptom onset may help to differentiate an acute from a chronic process, such as nonreducible joint subluxation. Most important is to determine if the loss of ROM is fixed or likely to be successfully ranged, as a chronic ROM limitation may indicate ankylosis or autofusion of a joint. Passive and active ROM testing should be performed to rule out weakness as an etiology for ROM limitation.

*Joint swelling* should be documented by onset, persistence, location, and quantity (i.e., serial circumference measurements). This helps differentiate acute inflammatory from non-inflammatory involvement. The former is best not treated with heat while the latter can be treated easily with either a heat or cold modality. When pain is noted with swelling, synovitis or bursitis may be present.

It is important to differentiate *weakness* from fatigue. Careful documentation of patient reports on muscle groups involved and relationship to functional limitations is needed. Proximal muscle weakness may be indicative of inflammatory myopathy such as PM. Persistent rather than intermittent complaints of weakness may indicate other processes, such as neuromuscular disease (e.g., Guillain-Barré's syndrome).

*Fatigue* may be one of the earliest symptoms. Some patients may have these complaints even though pain and swelling have been objectively controlled.

### Biomechanics

Evaluation of mobility can be performed with visual analysis or automated measures. The former has been standardized, and the latter have been significantly advanced with video-based high-speed systems. There is an increased ability to reliably measure motion in three dimensions: in real time, ground reaction forces, and pressures on the bottoms of the feet to calculate moments of force at various joints. These procedures are now more available and being performed fairly frequently. In addition, newer instrumentation has been developed to describe foot pressure profiles and describe forces and their influences on the foot (28).

Gait abnormalities for several RDs have been noted. The RA gait has been termed *apropulsive* because of the absence of pushoff from the ball of the foot. Similarly, studies of differences in gait before and after surgical procedures have been reported that describe which biomechanical changes occur as a result (29).

### Laboratory Tests

The laboratory evaluation of blood, urine, and synovial fluid, coupled with radiographic evaluations, history, and physical examination information, can usually help to establish a proper diagnosis. The following initial determinations are made: complete blood count, ESR, SMA 12 (sequential multiple analyzer), RF, and antinuclear antibody (ANA). An HLA B27 determination is performed if spondylitis is suspected. The acute-phase reactants (C-reactive protein [CRP], serum amyloid A [SAA], and ESR) should be monitored, as they may be part of the early defense or adaptive mechanisms that precede the immune response. Although nonspecific, moderate elevation in CRP and serum amylase can be seen in systemic diseases.

Joint fluid is easy to obtain in the presence of effusion. Analysis of fluid is essential in the diagnosis of crystal-induced arthritis and infection, and it is helpful in differentiating traumatic from inflammatory arthritis. However, rarely will the diagnosis of RA, OA, PSA, or AS be made on the basis of joint fluid alone. Rather, the fluid helps confirm a diagnosis. Joint taps must be done when a question of infection is raised and should be made before injecting steroid or other material into the joint. Classification of joint fluid into categories will help differentiate inflammatory, noninflammatory, septic, and hemorrhagic arthritis (see Table 40-1).

### Radiographic Assessment

Radiography is often the most valuable technique for differentiating among arthritides. Carefully selected radiographic series with the proper projections, addition of stress, and weight-bearing views will add valuable information about the extent of soft tissue, articular surface, or bony changes. Marginal erosion of bone with juxtaarticular OP is the hallmark of RA. Nonuniform joint space losses, in association with bony sclerosis and marginal osteophytes, are the characteristic changes in OA. Spondyloarthropathies classically involve the sacroiliac joints, either symmetric, as in AS, or asymmetric, as in RS and PSA. Bony changes include periosteal new bone formation and ankylosis. Gout and pseudogout often involve only a few joints. In gout there are soft-tissue tophaceous deposits and marginal erosion with large bony overhangs, and in pseudogout there is calcinosis in fibrocartilage. Early in joint infection, the x-ray films may be negative, or there may be some joint space widening. If the process continues and osteomyelitis develops, periosteal reaction can occur, which may indicate progressive infection or bony destruction. Table 40-2 presents typical radiographic findings in patients with RDs.

Additional imaging such as computed tomography (CT), which gives good structural definition of soft tissue and bone, is often combined with arthrography to study axial structures in disorders such as sacroiliitis. Magnetic resonance imaging (MRI) allows further differentiation of soft tissue and fluid as well as use of variable imaging planes and combination. Gadolinium for contrast is of great benefit in the evaluation of joint effusions, tendonopathies, and myositis

(30). Ultrasound may be useful in evaluating this patient population as well (31).

### Functional Assessment

Rehabilitation assessment for patients with RDs includes both process and outcome measures. Goniometry, the measurement of joint ROM, is standardized and widely used, as is manual muscle testing (MMT). A new ten-point MMT with specific grade definitions has been devised and offers more sensitivity in the strength range that is most important to know for assessment of capability for independence (32). Quantifiable measures of spine motion are particularly useful for patients with RDs (33). They can help chart progressive loss of spinal mobility, which prompts interventions designed to preserve posture as well as chest expansion programs, as in the management of patients with spondyloarthropathies.

Patients with arthritis often have stiffness rather than pain that limits function. Both symptoms are difficult to measure. However, duration of morning stiffness may be quantified. Pain can be measured in terms of severity in a descriptive way (e.g., mild, moderate, severe) or by use of a visual analog scale (34), which is quite reliable. Measures of degree of joint tenderness, swelling, deformity, relative instability, or crepitus with active and passive movement are also useful in defining RD processes.

Fatigue is a frequent problem for patients with RD. Its cause is multifactorial: medication, chronic inflammation, abnormal posture and gait that are energy inefficient, abnormalities of the sleep cycle, and atrophy of muscle secondary to disease or chronic pain. Fatigue is difficult to quantify. A visual analog scale has been used in the subjective measurement of fatigue but it has an imprecise reference. A multidimensional assessment of fatigue (35) has been devised and validated in this population. The fatigue severity scale has also been used to assess this parameter (36). The human activity profile (HAP) is an instrument designed to measure the amount of activity and those activities that an individual is no longer able to perform. It also has a dyspnea scale. Specific activities have been correlated with metabolic equivalents required for performance (37).

Despite reliable, sensitive indices of strength, ROM, and grip strength, other measures are needed for evaluation of patients with RD. The American Rheumatism Association in 1949 devised a functional scale for patients with RA. This scale, a simple, global assessment that rated patients' functional status as independent (i.e., class I), able to perform with pain (i.e., class II), able to do some activities (i.e., class III), and unable to perform (i.e., class IV) was revised in 1992 (38).

Two generations of functional assessments have been used in evaluating patients with RD. The first set looked primarily at performance of patients in ambulation, self-care, and other activities of daily living (ADL). Most had some testing of reliability and validity, and were relatively easy to use. The problem with them was that they defined function very narrowly and excluded psychological, social, and vocational functions. The newer functional indices are more comprehensive and offer a broader view of patients' functioning. These global, multidimensional tools had been designed for the arthritis

**TABLE 40.6** Functional Measures in RDs

population, children and adults, and have demonstrated validity and reliability (39,40).

When rheumatologists were asked which functional measures were important to use in the evaluation of patients with RDs, the consensus was mobility, pain, self-care, and role activity (41). The evaluations needed may vary, because some RDs involve only joints (e.g., OA); others, primarily kidneys, skin, and central nervous system (e.g., SLE); and still others, different organ systems, such as cardiovascular and pulmonary systems. Table 40-6 identifies standard functional measures likely to be needed for each of the RDs. Other useful scales include The Wisconsin Brief Pain Questionnaire, The sickness impact profile (SIP) (42), Stanford health assessment questionnaire (HAQ) (43), Short form 36 (SF36) version-2 (44), arthritis impact measurement scale-2 (AIMS-2) in RA and Osteoarthritis (OA), (45) and Bath and Duogados functional indices in spondylitis (46). These functional assessment tools singly and in combination are valuable tools for measuring both physical and psychosocial health parameters (Tables 40-7 and 40-8).

Functional assessment tools are also used in combination with traditional measures of disease state, including tender and swollen joint counts (number of tender and inflamed joints), and biochemical markers of disease state such as the acute-phase reactants. The combination of these tools into core set outcome measures is used to define clinically significant improvement in

diseases such as RA. The ACR has chosen the definition of 20% improvement in tender and swollen joint counts and improvement in three of the five following ACR core set measures: patient or physician global assessments of disease severity, pain, disability, and an acute-phase reactant level (47). This is commonly referred to as the ACR-20. Clinical improvement in the preceding core set measures that constitutes improvement of 50% and 70% (ACR-50 and ACR-70) are often referred to in randomized control trials. The Outcome Measures in Rheumatology Clinical Trials (OMERACT) group has reached consensus on the required core set measures of use in OA (48) and AS (49). Core set outcome measures in other populations, such as those with DM-PM, are currently in development. Although these tools are easily administered, results are often not immediately available for use because of scoring schemes. Some of these tools (e.g., HAQ) also have limited use because of ceiling effects and often miss subtle changes in the patient's disease process reflected in level of function; others may have significant flooring effects.

In the clinical setting of RA, a combination of factors including specific clinical and laboratory values are used to produce a disease activity score (DAS28). The DAS28 is derived from the number of tender and swollen joints, patient assessment of disease activity via visual analog scale, ESR, and CRP (50).

## Compliance

It has long been recognized that a number of factors may influence compliance of patients with treatment in general:

1. Demographic features
2. Nature of the disease
3. Therapeutic regimens
4. Setting in which treatment is given
5. Patient-doctor relationship
6. Sociobehavioral features of the patient

Compliance depends on individual health beliefs, including the importance to the patient of the treatment goal, how likely the treatment is to achieve the goal and benefit the patient (51), and how likely the treatment is to lessen the disability and the physical, psychological, and functional barriers to treatment.

In our clinical experience, patients who have pain are more likely to be compliant with medication, modalities, and techniques that relieve the pain. Education significantly increases adherence to drug regimens (52). Group education enhances self-management strategies (49).

One study of adolescents with chronic diseases (including JIA) indicated that good motivation was likely to result in better treatment compliance. Support from parents, physicians, and friends also predicted good compliance with regimens (53).

Compliance with the use of splints/orthotics has been low due to cosmesis, uncomfortable fit (more likely with noncustomized items), and fear that wear at work may jeopardize job status.

Likewise, compliance with unsupervised exercise programs tends to be low. In one study, two out of three patients with some form of arthritis management information used some technical orders and rest daily, and 50% used exercise and heat (25% on a daily basis) (54). Compliance at the 1-year level in patients on a home exercise program was predicted by self-efficacy for exercise, regular ROM before study intervention, and single marital status (55). Perceived benefit of exercise was a significant predictor of participation in an aerobic exercise program. Those who reported exercising in their youth perceived more benefits. Subjects with less formal education, longer arthritis duration, and higher impact of arthritis scores perceived fewer exercise benefits (56).

Compliance with splint use has been shown to increase when patients learn the purposes of use, expectations of use, and precautions for wear and when the splint provider has a positive affective tone and gives encouragement (57). Strategies to improve compliance with exercise can be seen in Table 40-9, and Table 40-10 lists strategies for improving compliance with orthotics and gait aid.

## TREATMENT

### Pharmacologic Management

Pharmacologic management of RDs often requires the use of one or more of a variety of medications, the pharmacology and pharmacokinetics of which may influence physical and psychological functioning. The well-known “treatment pyramid” approach to the management of RA and other RDs was in the past based on use of initial rest, patient education, joint protection, and nonsteroidal anti-inflammatory drugs (NSAIDs) with progression to steroids and sequential monotherapy, and use of DMARDs later in the course of these diseases. This treatment approach has undergone revision with improved knowledge of the rate of disease progression, prognosis, and

**TABLE 40.9 Strategies to Improve Compliance with Exercise**

Establish exercise dialogue between doctor and patient
Educate patient and family on exercise benefits
Write instructions for exercise
Make program simple
Provide diagrams of exercise
Be specific about exercise duration, frequency, and intensity
Have patient keep an exercise diary
Manage pain before exercise (medication or modalities)
Do exercise in late morning or early afternoon
Do supervised exercise (individual or group)
Give feedback to patient about exercise programs
Incorporate exercise into daily routine (particularly, with children)
Have parent monitor child's exercise
Phone patient to inquire if there are any questions about exercise

**TABLE 40.10 Strategies to Improve Compliance with Orthotics and Gait Aids**

Use custom orthotics for good fit
Explain purpose of preparations and benefits of orthotics
Use creative colors for hand orthotics
Educate on availability of silver/gold ring splints
Wear slacks over lower-extremity orthotics
Use scarves over neck collar
Educate on availability of hollow acrylic canes with scarf inserts
Educate on availability of metallic canes of different colors and colorful children's walkers

severity at presentation. DMARDs are used earlier and often in combination (Fig. 40-2) (58). At the onset of disease symptoms and diagnosis, the patient would begin early rehabilitation interventions: education, orthotics, physical modalities, joint protection, energy conservation, and strengthening, along with NSAIDs and low-dose steroid therapy in some cases. As we ascend the pyramid, introduction of DMARDs used singly or in combination and earlier use of biologic agents is noted. The time interval at which new agents or dosage changes are made has also been shortened.

### Aspirin

Aspirin, or acetylsalicylic acid (ASA), has been the foundation of management of rheumatic conditions and the symptoms of

pain, fever, and inflammation. It has been shown to block the synthesis of PG in the anterior hypothalamus, which is responsible for the antipyretic effect. The analgesic effect of ASA is not entirely understood. Musculoskeletal pain may be mediated by bradykinin, a synthesizer of PG, which sensitizes nerves to painful stimuli. Aspirin blocks PG synthesis. At doses higher than those used for analgesia (e.g., 5.3 g/day), ASA reduces joint inflammation and swelling. The mechanisms for this action are multifactorial. Aspirin affects leukocyte migration and vascular permeability, both of which may be influenced by PG synthesis. The toxicities of ASA include allergy, tinnitus and hearing loss, GI blood loss, ulcer, chemical hepatitis, and reduced glomerular filtration rate. For patients who have clinically significant GI symptoms, enteric-coated preparations are usually well tolerated. Other forms of salicylate can be used that are often less GI toxic (e.g., choline salicylate).

### Nonsteroidal Anti-inflammatory Drugs

The agents that form the group of drugs called NSAIDs, which include the cyclooxygenase-2 (COX-2) inhibitors, continue to be used in part as first-line agents in the management of RDs. These drugs also suppress inflammation through the inhibition of synthesis of PG. They inhibit the COX effect on platelets and effects on leukocyte migration. Toxicities include GI bleeding, pancreatitis, hepatotoxicity, decreased renal blood flow, hypertension, peripheral edema, and allergic interstitial nephritis. Some have more GI toxicity than others and cause more sodium retention. A review of the comparative NSAIDs toxicities is available (59).

**FIGURE 40-2.** Pyramid of the medical and rehabilitation treatment approach to inflammatory arthritis. (*Asterisk:* Patient education, adaptive equipment and strategies, modality use, and other non-pharmacologic Rehabilitation Medicine associated therapies.)

Diclofenac and misoprostol (Arthrotec)
Etodolac (Lodine)
Ketorolac (Toradol)
Nonacidic
Nabumetone (Relafen)
COX-2 inhibitors
Celecoxib (Celebrex)

NSAIDs were widely used as first-line drugs in the treatment of RA, JRA, OA, and the spondyloarthropathies but have more recently been replaced by the early use of DMARDs in some cases. Only tolmetin sulfate, choline magnesium trisalicylate, ibuprofen, and naproxen sodium have been approved for use in children by the U.S. Food and Drug Administration. A list of those commonly used NSAIDs in the United States is provided in Table 40-11.

Aspirin and NSAIDs are likely to provide significant clinical relief for patients with OA, RA, JIA, gout, and spondyloarthritis. These drugs are not usually effective by themselves in controlling RA and vasculitic syndromes.

The newest group of NSAIDs, the COX-2 inhibitors, has found more recent favor. They differ from traditional NSAIDs that do not inhibit COX-1 at normal therapeutic levels, thus likely avoiding some of the detrimental GI effects of other NSAIDs. Celecoxib has been shown to be effective in reducing joint pain and stiffness in RA (60). Rofecoxib has been withdrawn from the markets due to an increased risk of cardiovascular events.

### Glucocorticoids

Glucocorticoids and therapeutics for RDs are inseparable and probably have been tried in every RD either systemically or locally. Exogenous glucocorticoids influence leukocyte

movement, leukocyte function, and humoral factors; inhibit recruitment of neutrophils and monocytes into inflammatory sites; cause lymphocytopenia by inducing margination or redistribution of lymphocytes out of the circulation; modify the increased capillary and membrane permeability that occurs at an inflammatory site, reducing edema and antagonizing histamine-induced vasodilation; and inhibit PG synthesis.

Daily high-dose steroid use stimulates Cushing's syndrome, in which hypertension, hirsutism, acne, striae, obesity, psychiatric symptoms, and wound-healing problems occur. With exogenous doses above 12.5 mg/day, there is an increased incidence of glaucoma, cataracts, avascular necrosis, OP, and pancreatitis. The side effects are, in part, dependent on the particular glucocorticoid used and the dose. Alternate-day steroids are associated with fewer untoward effects. Current recommendations to reduce bone loss in patients receiving a prednisone equivalent of more than 5 mg/day include (a) use of supplemental calcium and vitamin D or activated form of vitamin D, (b) use of bisphosphonates, or calcitonin as a second-line agent for those with contraindications or intolerance to bisphosphonates, (c) hormone replacement therapy in those found to be hormone deficient (61). The oral route is usually selected for ease of administration, but glucocorticoids can safely be given intramuscularly, intravenously, or intra-articularly.

Glucocorticoids are used to treat several RDs. In 2002, a consensus conference made the following recommendations for a standardized nomenclature for glucocorticoid dosing. Doses of less than 7.5 mg—low dose, 7.5 to 30 mg/day—medium dose, 30 to 100 mg—high dose, greater than 100 mg/day—very high dose, and pulse-dosed therapies given at greater than 250 mg/day (62). Higher doses are used in treating patients with SLE, vasculitis, and DM-PM (up to 100 mg prednisone every day) (63). The benefit of steroid therapy to patients with AS, PSS, and PSA has not been shown.

### Disease-Modifying Antirheumatic Drugs

#### Methotrexate

This cytotoxic agent has become one of the first line agents in the treatment of moderate to severe RA. It is a structural analog of folic acid and causes the deficiency of intracellular folate by inhibition of dihydrofolate reductase, an enzyme required for DNA synthesis. This may not be the true mechanism of action that makes methotrexate (MTX) an effective anti-inflammatory agent. MTX also may act to promote the extracellular adenosine release which promotes the down regulation of inflammatory pathways by binding surface receptors on lymphocytes, monocytes, and neutrophils and inhibit interleukin production.

MTX has been shown to be effective in RA, JRA, SLE, and PSA and is effective in combination with corticosteroids in the management of some vasculitic conditions. It can be given in an oral form once per week at doses of 7.5 to 15 mg/week. Maximum doses of 25 mg/week may be given. Weekly subcutaneous or intramuscular injections are well tolerated and are associated with less GI side effects. Side effects include increased liver transaminases,

myelosuppression, pneumonitis, cirrhosis, increased risk of infection, and can be highly teratogenic.

### Hydroxychloroquine

Antimalarials, such as hydroxychloroquine (HCQ), are effective in discoid lupus erythematosus and SLE. Improvements in skin involvement, arthritis, and arthralgias are noted. They can also be effective in patients with RA with improvements noted in joint count, grip strength, walk time, and sedimentation rate. The antimalarials are slow-acting, taking 4 to 6 weeks before a therapeutic effect is observed. They are as effective as some of the other DMARDs, but a lower toxicity profile makes them one of the agents of choice in combination therapy (64,65).

The mechanism of action of these drugs is varied. They have been shown to impair enzymatic reactions, including phospholipase, cholinesterase-hyaluronidase, and proliferation of lymphocytes. They seem to block depolymerization by DNAase and interfere with DNA replication. The incidence of side effects and toxicities varies widely. GI disturbance is quite common, and retinopathy is infrequent but of greatest concern; it rarely occurs before a cumulative dose of 300 mg is reached, specifically in chloroquine, but routine ophthalmologic examinations should be performed. The antimalarial agents are most often used in the treatment of RA and SLE.

### Sulfasalazine

Sulfasalazine (SSA) is an agent that combines the antibiotic sulfapyridine with the anti-inflammatory agent 5-aminosalicylic. Its proposed mechanisms of action include inhibition of folate-dependent enzymes similar to MTX, immunomodulatory functions that decrease immunoglobulin and RF production, and several anti-inflammatory properties (66). SSA has been shown to be effective in treating RA, JRA, AS, and PSA.

### Leflunomide

Leflunomide is an immunosuppressive drug that inhibits *de novo* pyrimidine synthesis and impairs T-cell proliferation. In the treatment of RA, this drug has been shown to be as effective as MTX (67). This agent has been shown not only to be effective as monotherapy but also to be even more effective when used in combination with MTX; however, concerns remain over the toxicity profile (68). Leflunomide is shown to be effective in the treatment of RA, SLE, and PSA. Monitoring while on this medication includes (a) liver function tests for toxicity and (b) platelet count for signs of thrombocytopenia.

### D-Penicillamine

D-penicillamine has been effective in the treatment of seronegative or seropositive RA but has not been used as often due to the associated high incidence of toxicity (69). The patterns of response to penicillamine are similar to those observed with gold. Toxicities include leukopenia, thrombocytopenia, proteinuria, skin rash, stomatitis, GI upset, and a variety of autoimmune syndromes, including Goodpasture disease, PM, and SLE. The mechanism of action is unknown, but it is neither cytotoxic nor anti-inflammatory.

### Immunoregulatory Agents

Immunoregulatory drugs have been used in the management of RDs in an attempt to restore a balanced immune response by eliminating certain cell subsets. None of these drugs have cured patients with RDs, but they have produced some disease control and long-term remissions (70). Commonly used agents are the alkylating agents (cyclophosphamide and chlorambucil), purine analogs (azathioprine and meraptopurine), cyclosporine, tacrolimus, sirolimus, mycophenolate mofetil, dapsone, and thalidomide.

#### *Cyclophosphamide and Chlorambucil*

Cyclophosphamide and Chlorambucil are alkylating agents that form active metabolites that cross-link DNA, preventing replication, and reducing DNA synthesis. Immunoregulatory effects are through the decrease of both T and B-lymphocyte proliferation, antibody production, and suppression of delayed hypersensitivity reactions to new antigens. Cyclophosphamide has been shown to be effective in treating SLE and RA, while chlorambucil is utilized for RA. These agents have toxicity profiles that include myelosuppression, increased risk of infection, and risk of malignancy (70).

#### *Azathioprine and Meraptopurine*

The purine analogs, azathioprine and meraptopurine, are converted to thiopurine, metabolized, and incorporated into cellular DNA, leading to inhibition of nucleic acid synthesis. Through this mechanism, it is believed that these agents function to decrease circulating lymphocyte count, suppress lymphocyte proliferation, inhibit antibody production, and inhibit monocyte production as well as cell mediated and humoral immunity (70). These agents have been used to treat RA and SLE and are well tolerated. The most common side effects include GI symptoms, myelosuppression, and risk of infection.

#### *Cyclosporine*

Cyclosporine exerts its effects by inhibiting the production of interleukin-2 and other cytokines, leading to reduction in T-cell activation and lymphocyte proliferation. It has been used in the treatment of RA and PSA. Toxicities include GI upset, hypertension, nephrotoxicity, and increased risk of lymphoma and skin cancer. Tacrolimus, a macrolide, functions by binding to an intracellular binding protein (FK-binding protein) and in association with calcineurin suppresses the transcription of cytokines and inhibits the early steps of T-lymphocyte activation (71). Sirolimus also binds to the FK binding protein but functions through blocking the progression of the cell cycle, inhibiting cell signal transduction (72). Mycophenolate mofetil is converted to Mycophenolate acid that reversibly inhibits inosine monophosphate dehydrogenase, an enzyme required for the synthesis of purines, thus inhibiting T- and B-cell lymphocyte proliferation. It has been used in the treatment of SLE and associated nephritis.

**TABLE 40.12 Therapeutic Application of Drugs in RDs**

Diseases	Recommended Medications	Probable Mechanisms	Precautions
RA	ASA, NSAIDs Antimalarials Gold D-penicillamine Steroids Azathioprine Methotrexate Cyclophosphamide Cyclosporine Biologic agents Infliximab/etanercept Leflunomide Sulfasalazine Minocycline	Inhibition of COX enzyme needed for PG synthesis Block lysosomal enzymes Inhibits phagocytic activity of macrophages Unknown Interfere with lymphocytic migration; decreases intra articular membrane permeability Inhibits DNA synthesis Causes intracellular folate deficiency Prevents DNA replication Inhibits IL-2 production Inhibits TNF Inhibits pyrimidine synthesis, cell activation and adhesion Suppress lymphocyte and leukocyte fxn  Upregulation of IL-10 (anti-inflammatory cytokine)	Bleeding diathesis (platelet dysfunction) Upper GI toxicity Renal toxicity Retinal toxicity, psoriasis Nephritis, rash, marrow suppression Nephritis, SLE, PM Lymphoid tumors Not used with allopurinol Cirrhosis, leucopenia Marrow suppression, liver toxicity, lung fibrosis Ovarian cystitis Nephrotoxicity, hypertension, ↑ infection risk Injection site rxn, ↑ infection risk  Alopecia, stomatitis, abdominal pain, ↑ LFTs, hypertension Hepatitis, marrow suppression, rash diarrhea GI toxicity, rash

GI, gastrointestinal; PG, prostaglandin; RA, rheumatoid arthritis; DNA, deoxyribonucleic acid; TNF, tumor necrosis factor; ASA, acetylsalicylic acid; SLE, systemic lupus erythematosus; COX, cyclooxygenase; PSS, progressive systemic sclerosis; DM-PM, dermatomyositis-polymyositis; LFTs, liver function tests; NSAIDs, nonsteroidal anti-inflammatory drugs.

Thalidomide, a derivative of glutamic acid, is believed to exert its immunosuppressive effects through the inhibition of angiogenesis and tumor necrosis factor (TNF)- $\alpha$ . Its most notable toxicity is as a potent teratogen but it is also associated with peripheral neuropathy. Currently only approved for the treatment of erythema nodosum, studies are looking into its

use in RA, SLE, Sjogren's syndrome, and AS (73). Dapsone, an antimicrobial agent, is believed to affect the neutrophil function by decreasing recruitment, chemotaxis, and inhibiting neutrophil function (74). These drugs cause marrow suppression and GI intolerance. A review of the therapeutic application of these drugs is presented in Table 40-12.

### Gold

Parenteral gold, and more recently oral gold (auranofin), has been used in the treatment of synovitis in patients with RA. Gold is thought to work by inhibiting lysosomal enzymes or by inhibiting phagocytic activity in macrophages and polymorphonuclear leukocytes. It also inhibits aggregation of human  $\gamma$  globulin *in vitro*, a phenomenon that is thought to be an inflammatory antigenic stimulus in RA. These events have been observed when parenteral gold is used. The oral preparation alters all mediated immunity, inhibits DNA synthesis *in vitro*, and suppresses humoral immunity (75).

Adverse effects of gold compounds include rash, stomatitis, proteinuria, and hematologic disorders (e.g., leukopenia, thrombocytopenia). These side effects, combined with lack of long-term clinical efficacy, have led to decreasing use of the agent. This drug is not used in patients with SLE, partly because it may flare the skin involvement. It may be useful in treating patients with peripheral arthritis associated with psoriasis.

### Antihyperuricemic Agents

Pain and inflammation of crystal-induced arthritis are frequently adequately controlled with NSAIDs. Although these drugs are effective in controlling symptoms, they do not alter the metabolism of the substances forming crystals, nor do they influence their excretion. Uricosuric agents like probenecid compete with the tubular transport mechanism for uric acid, reduce the reabsorption of uric acid, and hence increase its excretion (76). Their use is widespread, and their toxicities are well known, including nephrolithiasis, which is preventable if the urine is alkalinized and fluids are increased. Acute gout can be precipitated as the uric acid levels are lowered and GI symptoms are not infrequently seen. A second approach toward controlling serum urate levels is that of regulating production of uric acid by inhibiting xanthine oxidase. This is done by using allopurinol as an analog of hypoxanthine. It too can precipitate an acute attack of gout and can cause xanthine renal stones. Side effects include rash and, rarely, blood dyscrasia. Allopurinol should not be used with azathioprine. Allopurinol is an inhibitor of the principal pathway for the detoxification of azathioprine.

### Biologic Agents-Anticytokine Therapies

Etanercept (administered subcutaneously), infliximab (administered intravenously), and adalimumab (administered subcutaneously) function to inhibit TNF and have gained increasing popularity, as studies have shown these to be as effective, if not more effective, in preventing joint damage than MTX (77). Infliximab and adalimumab are monoclonal antibodies and bind to TNF- $\alpha$ . Etanercept binds both to TNF- $\alpha$  and lymphotoxin  $\alpha$ , neutralizing their biologic activity. It is administered in doses of 25 mg twice weekly or 50 mg once weekly. It has been shown to be effective in RA (78), AS (79), and PSA (80). The most significant side effects include injection site reactions and infections, and to a lesser extent development of autoantibodies. There is also some risk of lymphoproliferative disorders and more rarely

lupus-like reactions, demyelinating disorders, as well as other malignancies (81).

Anakinra (administered subcutaneously) is an anti-interleukin-1 receptor antagonist, currently approved for the treatment of RA. Doses of 1 and 2 mg/kg were shown to make improvements in joint counts, pain scores, morning stiffness, and physician assessment of disease activity (82).

### Other Biologic Agents

Two of the newer biologic agents include rituximab and abatacept. Rituximab is a monoclonal antibody directed against the extracellular domain of the CD20 antigen on B-Cell and initiates complement-mediated B-cell lysis. Abatacept binds to CD80/CD86 on the surface of antigen presenting cells and inhibits T-cell activation. These agents continue to be studied but have shown significant promise for the treatment of RA when used in combination with MTX (83,84).

### Combination Therapies

Along with a shift of the classic treatment paradigm for RDs by using DMARDs earlier in the course of disease, it has become increasingly more common to use these agents in combination. The benefits of using some of these combination therapies include additional therapeutic effects of drugs that may not have been fully effective as monotherapy and possible improvement in the toxicity profile, as lower doses of these potentially toxic agents are needed. MTX is commonly used in combination with other DMARDs. Often used combinations include the following:

1. Cyclosporine and MTX have shown to be very safe and useful in the treatment of severe RA (85).
2. MTX, HCQ, and SSA combination therapy has shown some promise with moderate efficacy and no noted increased toxicity when compared with MTX alone or SSA/HCQ in combination (86).
3. MTX and TNF- $\alpha$  blocking agent infliximab showed good overall drug tolerance and sustained efficacy over a 2-year period (87).
4. MTX and leflunomide as a combination has shown some associated drug toxicity but a good overall efficacy (88).

Many other combinations of these agents have been evaluated. Some have shown promise but others have been marred by intolerable side effects (89).

### Complementary and Alternative Medicine

The National Institutes of Health defines complementary and alternative medicine (CAM) as encompassing those treatments and health care practices that are not widely taught in medical schools, not generally used in hospitals, and not usually reimbursed by medical insurance companies. These therapies are sometimes called *unconventional therapies*, since they are outside the “mainstream of Western medicine.” Often these therapies have not undergone rigorous scientific analysis in randomized controlled trials (RCTs) (89–92). More medical schools have now introduced CAM into their curriculum (93).

The term *alternative* alone has been used to refer to practices used in place of mainstream Western medicine, such as exclusive use of herbs instead of prescription drugs. The Arthritis Foundation (AF) prefers the term *complementary medicine* for the use of unconventional therapies in arthritis that are used to support mainstream Western medicine.

There has been an increasing use of CAM in the general population to treat disease. One recent study (94) indicated that 42% of patients use at least one of 16 CAM therapies, and 50% of these patients had musculoskeletal disease. The study indicated that CAM is used as an adjunct to conventional therapies. Visits to CAM practitioners exceeded those to primary care physicians, and patient expenditure was \$27 billion/year, similar to expenditures for all U.S. physician services.

Because of the chronic painful nature of RDs and the fact that they often are not cured by Western medicine, arthritis patients often seek CAM treatments (95). A 1998 review of surveys indicates use by 30% to 100% of arthritis patients. A 2004 study showed 90% of primary care clinic patients with arthritis use CAM, and RA patients used an average of 4.4 CAM therapies (96). A 2004 study revealed 33% of JIA patients use CAM as parents sought it for pain relief for their children (97). However, only 38% to 55% of patients reveal their use of CAM to their physicians (95). A more recent study cited 70% of RA patients revealed their CAM use to physicians (96). Physicians should ask patients about their use of CAM, as some treatments are contraindicated when used with conventional therapies (98). Arthritis patients and physicians have different perceptions about the usefulness of CAM. Arthritis patients generally perceive its usefulness (99). In a group of mixed arthritis patients in a 2005 review, homeopathy and acupuncture were the most used type of CAM (44% and 41%, respectively). Significantly higher self-perceived efficacy scores were seen for CAM use in patients with spondyloarthropathies and OA. The lowest scores were among RA and connective tissue diseases (100). Some rheumatologists do not recommend them (101) and others do (102). The general trend is toward more approval by health care providers.

A number of practitioners and treatments are included under CAM (Table 40-13). The main categories are alternative healing systems; mind, body, and spirit treatments; prayer and spirituality; moving medicine; massage and touch; herbs and supplements; and miscellaneous treatments. In one study, RA patients most commonly used relaxation, glucosamine, and vitamin C. There was less common use of fish oil and gamma-linolenic acid (GLA) containing supplements. Patients used therapies to relieve pain, prevent disease progression, and to feel better (96).

The benefit of some CAM therapies has been researched, while others have been minimally studied. Much of the older research consists of nonrandomized, noncontrolled trials. The issue of efficacy of popular CAM therapies (acupuncture, herbs, or homeopathy) used by the general population has been explored in recent meta-analysis reviews of controlled trials (103–105). The publications listed in references (72) and

(87–94) are available for review of CAM benefits. Most of the literature refers to neck and back pain, fibromyalgia (FM), and OA. The literature is sparse on the benefits of CAM in inflammatory arthritis.

There continues to be a growing interest in the use of herbal therapies in RA. A systematic review of RCTs in this area resulted in 14 such trials. There was moderate support for GLA for reducing pain, joint count, and stiffness. Further research is needed to examine the safety and efficacy of herbal remedies (106).

A 2005 review summarizes the efficacy and toxicities of herbal remedies used in CAM therapies for RDs. It elucidated the immune pathways through which they have anti-inflammatory and/or immunomodulatory activity that may provide a scientific basis for efficacy. For instance, GLA acts

as a competitive inhibitor of PG E<sub>2</sub> and leukotrienes (LTs). It appears to be efficacious in RA (107).

Proven benefits in noninflammatory arthritis include the following: (a) glucosamine/chondroitin decreases knee pain and slows disease progression in OA (108) and (b) acupuncture significantly decreases knee pain in OA (109).

Analysis of 17 acupuncture trials in 1997 (110) failed to show benefits of acupuncture in RA, SLE, AS, and PSS. AF reviews confirm this (91). In a 2005 systematic review of studies on acupuncture and electroacupuncture for RA, the reviews concluded that although electroacupuncture showed significant knee pain reduction 24 hours and 4 months posttreatment, the poor quality of the trial, including small sample size, precluded its recommendation. They further conclude from the studies reviewed that acupuncture has no significant effect on ESR, CRP, pain, patient global assessment, number of tender joints, general health, disease activity, and reduction of pain medications (111). A recent pilot study of two treatment groups of SLE patients (acupuncture or minimal needling) versus usual care revealed a more than 30% improvement in pain measures in the acupuncture and minimal needling groups with no improvement in the control-usual care group (112).

Other CAM modalities/treatments have also been studied. Low-level laser treatment decreased pain in RA in a Dutch study (113). A cognitive behavioral intervention (biofeedback) resulted in a decreased number of clinic visits and hospital days, and medical costs in RA (114).

A yoga program based on upper-body posture flexibility; correct hand, wrist, arm, and shoulder alignment; and stretching provided significant reduction in pain and increased grip strength in Carpal Tunnel syndrome (a common problem in RA) (115). An NIH consensus conference in 1998 concluded that acupuncture was useful for Raynaud's syndrome (a common problem in SLE, MCTD, PSS) (116). A study by Yocum indicated that biofeedback increased the fingertip temperature in Raynaud's syndrome in SLE and PSS (117). Intercessory prayer in one uncontrolled study significantly decreased the number of swollen joints, pain, and disability in RA patients (118). Tai chi is safe in RA but benefits are not proven. A 2007 systematic review of 45 studies of tai chi for RA, found only two RCTs and three non-randomized controlled clinical trials (CCTs) meeting the Jadad score for methodological quality. The RCTs demonstrated some positive findings for tai chi on disability index quality of life, depression, and mood but not on pain reduction. It was concluded by the author that collectively, at the current time, evidence is not convincing enough to suggest tai chi is an effective treatment for RA (119). A 1997 study indicated massage decreased pain and joint stiffness in JIA (120).

In general, diet can influence gout, but other than that, there is no definite evidence that diet can cure arthritis (72). There is some suggestive evidence that a decrease of omega fatty acids and substituting omega-3 oils may decrease pain and inflammation. Sources of omega-3 oils include cold-water oily fish, sardines, green soybeans, tofu, canola, and olive oils (89).

Most CAM therapies are low risk, but some do involve risks (89). Herbs can interfere with prescription medication. The following increased sensitivity to anticoagulants: bromelain, chondroitin, fish oil, GLA, garlic, ginkgo, ginger, ginseng, evening primrose oil. Folic acid interferes with MTX. Ginger can increase NSAID effects. Ginseng may increase the effects of glucocorticoids and estrogens, and should not be used in diabetes mellitus or with monoamine oxidase (MAO) inhibitors. Kava Kava increases the effects of alcohol, sedatives, and tranquilizers. Magnesium may interfere with blood pressure medication. St. John's Wort enhances the effects of narcotics, alcohol, and antidepressants, and increases the risk of sunburn and can interfere with iron absorption. Valerian increases sedative effects. Zinc interferes with glucocorticoid and immunosuppressive drugs (89).

Caution should be noted in patients with inflammatory arthritis receiving manipulation therapy. These patients often have damaged joints that can sublux (RA, JIA) (121) and ligamentous laxity (122). Patients with significant AS have rigid spines and can fracture. Those with moderate to severe OP from disease and steroids can also fracture. Spinal fractures can result in neurologic compromise. Patients with RA have C1-2 laxity or instability, and can sublux with neurologic compromise.

Precautionary advice in CAM administration includes use of only sterile disposable needles, and prohibiting the use of pulse electromagnetic field therapy in pregnant or cancer patients, and magnets in those with implanted electronic devices or electric blankets.

## **Surgery: Soft-Tissue and Reconstructive Procedures**

Indications for surgeries in the RDs include the restoration or preservation of joint mechanics and function, and relief of pain. In general, pain relief is a more predictable outcome in arthritis surgery than is functional restoration. Contributors to functional outcome include motor strength, motivation, post-operative complications, and participation in rehabilitation, all of which are highly variable.

The decision to operate on a patient with RD requires a thorough preoperative evaluation. This must include the overall health status of the individual and identification of the medications that might increase the risk of surgical complications. This population is likely to be more than 55 years of age, have an altered immune system, and be receiving medication that could influence healing. Examples of these medications include steroids, NSAIDs, MTX, and the newer cytokine inhibitors. Information about disease status and medication will help illuminate any additional risks for surgery.

Equally important is to perform a comprehensive physical examination and review of x-rays. The decision about which procedure to perform depends on properly identifying the cause of symptoms and the ability to determine whether they are likely to be correctable by the proposed procedure. Efforts to realign joints or soft tissue, although important, should be considered within the context of functional needs

and symptom control. For example, pain is usually the result of joint deformity and its sequelae, but nerve entrapment, referred pain, and myopathy might need to be ruled out before surgery.

Proper identification of potential risk factors for anesthesia, surgery, or postoperative course is also important. For example, C1-2 subluxation poses a significant risk for intubation. Carious teeth may increase the likelihood of developing postoperative infection. Obesity may make rehabilitation difficult and compromise the long-term outcome of surgery. These problems would need to be treated or accommodated before surgery.

Timing of surgery may be critical to outcome. For example, shoulder replacement in a patient who has had longstanding ROM deficits, in whom rotator cuff function is limited or absent, will have a poorer functional outcome than someone whose rotator cuff is still working. When possible, surgery should be considered before the development of significant joint contracture, muscle atrophy, and instability.

The surgical procedures relevant for joint and soft-tissue management include synovectomy and joint debridement, tendon repair and realignment, osteotomy, arthrodesis, and arthroplasty. Each procedure has specific indications. Much has been written about the success of these procedures, their life expectancy, and long- and short-term complications. Rehabilitation professionals can assist in preparing patients for optimal outcomes by assisting patients to achieve a higher preoperative level of fitness, helping set realistic expectations, and educating them about health and function-promoting behaviors. These might include developing a strengthening program for the hip girdle muscles for those undergoing hip surgeries, encouraging the use of a cane until the hip abductor is adequately strengthened and Trendelenburg gait is eliminated, and eliminating leg length discrepancies (123).

### Synovectomies

Synovectomies were first performed by Volkmann in 1877 for tuberculosis of the knee. Today they are sometimes performed on RA patients, most commonly to relieve pain and inflammation associated with chronic swelling uncontrolled by medication; to retard the progression of joint destruction, which is a controversial issue; and to prevent and retard tendon rupture. Other indications include the alleviation of decreased ROM caused by hypertrophied synovial tissue and denervation effect with reduced pain and inflammatory response.

Synovectomies are usually performed on the knee and wrist, and may be performed by arthrotomy or arthroscopically. They are most frequently done in hemophilic arthropathy, for pigmented villonodular synovitis or early RA.

Tenosynovectomy is most frequently performed for the extensor tendons of the hand. Regrowth of synovium commonly occurs postoperatively, so the procedure is not a curative one. Often local management using intra-articular injections of long-acting corticosteroids is tried, along with splinting of the joint when feasible and education to help develop alternative strategies that prevent overuse (124,125).

### Tendon Surgery

Tendon surgery is common in inflammatory disease. Frequent indications for surgery include repair of ruptured extensor tendons, realignment of tendons of the hand, synovectomies for tendons with severe tenosynovitis, and reanastomosis following tendon ruptures (Achilles and patellar tendons) and tendon releases for intrinsic tightness (126).

### Arthrodesis

Arthrodesis is performed less often today than in the past because of the popularity and success of joint replacement. It may still be the best procedure to eradicate resistant infection that has destroyed significant bone. The stability provided by an arthrodesis should be permanent. Adolescents and young adults with many more years of activity might well be considered for an arthrodesis in selected instances rather than a joint replacement, which often does not stand the stress placed on it by a young, vigorous patient. Arthrodesis for patients with arthritis is usually limited to the wrist, interphalangeal (IP) joints of the hand, first metacarpal phalangeal (MCP) joint, subtalar joints, and vertebral bodies. The triple arthrodesis remains one of the best procedures for reconstructing the hind-foot and restoring a pain-free, functional foot. Postoperative rehabilitation for this procedure requires 4 to 6 weeks of non-weight bearing, for which a rollabout can be prescribed for mobility. The rollabout is an ambulation aid, similar to a scooter, mounted 22 in. above the floor on four small wheels. It has a handle, a hand brake, and a padded shelf on which the leg is placed at 90 degrees of knee flexion. It is propelled by the nonoperative lower extremity and permits a reasonably rapid ambulation speed. The next level of independence is the cast boot and then a shoe with a custom insert and a rocker sole that assists in push off. Somewhat more controversial is knee arthrodesis, a procedure that is rarely done but is occasionally suggested for the very young and highly mobile patient.

Common indications for arthrodesis of a joint are to relieve persistent pain, to provide stability where there is mechanical destruction of a joint, and to halt progress of the disease (e.g., infection, RA). Joints should be fused in optimal functional position (127). Contraindications for arthrodesis include significant bilateral joint disease. Joint replacement is indicated more in this instance and arthrodesis of the same joint on the contralateral side.

### Joint Replacements

#### Upper Extremity

Upper extremity joint replacements have become more common today (128). Patients with RA, JIA, OA, and AN in SLE may require joint replacement. Common indications for replacement are persistent pain despite adequate medical and rehabilitative management, loss of critical motion in the involved joint, and loss of functional status.

The main contraindications for joint replacement are inadequate bone stock and periarticular support, serious

medical risk factors, and presence of significant infection. Other contraindications include lack of patient motivation to cooperate in a postoperative rehabilitation program and inability of the procedure to increase the patient's total functional level.

*Wrist arthroplasty* is recommended for those with adequate bone stock, who have relatively low use requirements. Loosening over time is common (129). MCP arthroplasty is performed for the preservation of function due to the relative frequency of subluxation and progression to dislocation in RA. Surgery performed before MCP dislocation usually has a better outcome (130).

*Elbow surgery* is usually restricted to radial head excision and arthroscopic synovectomy. Results from these procedures deteriorate over time (131). Elbow replacements have been shown to be effective in reducing pain and in improving ROM in pronation/supination, though improvement in flexion/extension is modest (132). Total elbow replacement has been recently used for patients with inflammatory arthritis with good success. Patients have noted substantial reduction in pain and improved functional ROM (133). Excision of the radial head, however, remains one of the best procedures for pain reduction and improvement in elbow ROM.

*Shoulder arthroplasty* has been shown to be beneficial in relieving pain. Older patients have better function and longer-lasting results than younger patients. Those with rotator cuff tears have 33% to 50% return of ROM following surgery, which is approximately half of those without significant tears that undergo arthroplasty (134). Long-term reports suggest that it is also associated with good functional outcome when rotator cuff function is intact (135). The shoulder is stiff, but flexion and abduction can be performed (<50 degrees) using scapulothoracic movement.

Indication for fusion of the cervical spine in patients with RA remains somewhat controversial. There is agreement that pain, unresponsive to nonsurgical treatment, cord compression, or peripheral sensory and/or motor loss are indications for cervical spine stabilization and/or cord decompression. Some studies suggest that early intervention is associated with better neurologic outcome. Instability of more than 10 mm at the atlantoaxial joint, or greater than 4 mm of basilar invagination suggests the need for spinal stabilization.

### **Lower Extremity**

Total hip replacement surgery has been performed in the United States for more than 30 years. More than 120,000 hip replacements are done annually, and function remains good 25 years after surgery (136). Hip surgeries are no longer limited to patients more than 60 years of age. Infection rates have been dramatically reduced to less than 1% (137). Loosening of the prosthesis is the reason for long-term failure. The acetabular component is more likely to loosen than the femoral component, even in younger patients (138). Uncommented acetabular and femoral components may offer greater prosthetic durability.

Hip replacement surgery offers patients with RA, SLE (avascular necrosis), and AS pain relief and improved function. The decision about whether to offer a cemented or noncemented prosthesis is usually based on the age and the functional requirements of the population to be treated. The older (>70 years of age) patients most frequently receive a cemented prosthesis, which provides good, immediate stability. The noncemented prosthesis is associated with better preservation of bone but may be associated with persistent thigh pain.

Patients are given prophylactic antibiotics before surgery and low-molecular-weight heparin the night of surgery and for the duration of the hospital stay. Antibiotic prophylaxis is recommended for dental work. A good discussion by Sledge of the operative and postoperative course is recommended to the reader (139).

Total knee replacement surgery is commonly used for patients with bi- and unicompartmental joint space destruction, persistent pain from poor joint mechanics, and functional loss. Long-term complications tend to result from uneven patellar surface wear and loosening. Total knee arthroplasty has provided excellent pain relief and good functional outcomes for arthritics. Studies report prosthetic longevity with sustained, excellent function for more than 12 years (140). Problems with the patellar components are the most significant cause of knee joint replacement failure.

Ankle replacement arthroplasties have not been demonstrated to be effective over time. Loosening remains the most serious complication (141). Those patients with very limited mobility who require ambulatory function may be reasonable candidates for this procedure. Forefoot arthroplasty with total resection of the metatarsal heads is an excellent pain-relieving procedure. This enables patients to walk on a pain-free foot, although the toes become floppy, the foot size is smaller, and the mechanics of pushoff, which are usually improved from the painful state, are not returned to normal. Use of a roller sole helps correct the dynamic abnormality (142).

### **Preoperative Rehabilitation Management**

To maximize postoperative gains, preoperative rehabilitation interventions are desirable. These interventions include teaching the patient crutch walking with the appropriate type of crutch; weight reduction for the obese patient; and strengthening of the quadriceps before knee replacement and the hip abductors before hip surgery. Orienting patients to the types of pain they may experience postoperatively—such as acute, incisional; muscle strain or fatigue; and nerve root irritation—may help allay fears about the stability of the hip. Descriptions of the usual course of recovery may also prepare them for what to expect.

### **Postoperative Rehabilitation Management**

The rehabilitation management goals of a total joint replacement program are to relieve pain, to redevelop comfortable musculoskeletal function, and to use joint protection techniques to avoid overstressing the prosthetic joint. The postoperative management of a hip replacement is individualized

based on the preferences of the orthopedic surgeon and the needs of the patient. However, the program usually includes bed mobility. ROM is started immediately with ankle pumps, and isometric exercise to the quadriceps. The patients are usually made to stand by the bedside with full weight bearing crutches if the hip is cemented, or partial weight bearing if it is uncemented. Patients are placed in an abduction sling and told to restrict hip flexion to less than 90 degrees and to limit adduction and internal rotation (IR). While in bed, they are to sleep in a supine position with a pillow between their knees for a month. They need to be carefully monitored for signs of deep venous thrombosis, fever, excessive wound drainage, and/or infection. Patients should be instructed to use an elevated toilet seat and an elevated chair seat to minimize hip flexion. Discharge from the hospital is usually on the fifth day, provided they can get in and out of bed independently, walk independently with crutches or walker, and manage stairs. Key exercises include quadriceps, hip abductor, and hip flexor strengthening. Patients should expect to use a cane until hip abductor strength is in the four (based on the medical research council [MRC] scale) range and there is no Trendelenburg sign. Many orthopedists permit return to full activity, including recreational tennis, cycling, and gardening (143).

The postoperative management of knee replacement includes the following procedures: Begin knee ROM immediately postoperatively, often with the aid of a continuous passive motion machine. Total weight bearing (to tolerance) with crutches and ad lib ambulation is started on the first postoperative day using crutches or a walker. Active assistive flexion is the cornerstone of management and usually needs to be done under supervision of the physical therapist. Knee replacement patients, unlike those undergoing hip replacement, frequently need some additional rehabilitation requiring admission to a rehabilitation center (skilled nursing level or if accompanied by significant comorbidities, an inpatient rehabilitation facility [IRF]).

The extent of rotator cuff repair and function in part dictates the nature of the post-shoulder arthroplasty rehabilitation program, but the postoperative management of total shoulder replacement usually includes the following: Immobilization of the shoulder for 2 to 8 weeks in an airplane splint with the shoulder in 80 degrees of flexion, 70 degrees of abduction, and 5 degrees of IR. Passive motion through range, in excess of where the limb is in the splint, is performed in the supine position. At the eighth to tenth postoperative day, active, assistive shoulder exercise is begun in the sitting position to 110 degrees of flexion and 20 degrees of external rotation (ER). At 6 weeks after surgery, active, unrestricted ROM is permitted, sometimes using an overhead pulley to assist in end range. Lifting up to 10 lb is permitted (144).

## REHABILITATION INTERVENTIONS

Rehabilitation treatment plans must be individualized for the patient's needs; they should be practical, economical, and valued by the patient to enhance compliance. Treatment should

begin early in the disease process to help prevent impairment and functional decline so that the patient identifies this as part of the overall management plan. There is scientific and clinical rationale for the use of some specific rehabilitation treatments; others are based on clinical judgment. Rehabilitative rheumatology treatments and techniques must be monitored carefully, and periodic reevaluation of the patient with adjustments in treatment should be made.

### Rest

Three forms of rest have been used by persons with arthritis: complete bed rest, local rest of a joint or joints with splints or casts, and short rest periods of 15 to 30 minutes dispersed throughout the day.

### Systemic Rest

In the 1960s and 1970s, the literature revealed studies supporting bed rest for up to 4 weeks for persons with RA to decrease the number of inflamed joints, joint stiffness, and disease activity. However, systemic rest has many adverse effects, including muscle weakness and bone loss. Currently, the approach to the management of RA has changed. Much more adequate pharmacologic management of disease activity exists, such as early treatment with DMARDs. In addition, the literature clearly supports mobilizing and exercising patients with inactive and subacute inflammatory arthritis and encouraging them to be proactive in maintaining fitness and healthy lifestyle behaviors through exercise and symptom control throughout the disease course.

Depending on the disease severity, shorter periods of complete bed rest than formerly used may be needed. Several days of bed rest may be indicated for severe new-onset RA, SLE, and PM and for severe acute flares during the course of these diseases when intravenous medication may be needed.

### Local Rest

Local rest of acutely or subacutely inflamed joints at night with nonfunctional resting splints and during the day with functional splints reduces inflammation and pain, and may help prevent contracture. Immobilization of the wrist for painful periarticular syndromes (e.g., de Quervain's syndrome and carpal tunnel syndrome) is useful to relieve pain. One ROM exercise daily for joints during rest of 2 weeks' duration is not noted to cause an adverse effect. In terms of muscle effect, 4 weeks of knee immobilization in nonarthritic population causes a 21% decrease in muscle mass determined by computerized tomography and biopsy (145).

### Short Rest Periods

Provision of short rest periods during the day of 20 to 30 minutes along with appropriate local splinting is considered the appropriate way to manage patients with inflammatory arthritis to help control joint inflammation and fatigue. Some workplace sites now provide rest areas for persons, complete with cots. Negotiation with employers may also result in a person with an office being allowed to keep a small cot or sofa for napping.

### Exercise

Arthritis commonly produces decreased biomechanical integrity of joints and their surrounding structures, which results in decreased joint motion, muscle atrophy, weakness, joint effusion, pain, instability, energy inefficient gait patterns, and altered joint loading responses (146,147).

Arthritis patients may lose muscle strength and bulk because of inactivity. A muscle can lose 30% of its bulk in a week and up to 5% of its strength a day when maintained at strict bed rest (148). Other factors contributing to loss of strength are myositis, myopathy secondary to steroids (149), inhibition of muscle contraction due to joint effusion (150), and direct effects of the disease itself on the muscle. For example, in RA, some destruction of muscle fibers occurs as well as intermuscular and perimuscular adhesions, which may impair blood flow. Muscle fascicles adhere to one another, and the entire muscle may adhere to the intermuscular septum and perimuscular fascia, causing inhibition of muscle contraction and normal movement (146) with RA, PM, SLE, and PSS. This results in weak, painful, and easily fatigable muscle. Reduced strength, as determined by isometric testing, has been documented in the quadriceps even in mild RA (151,152), PM (153), and JIA (154). Isokinetic strength testing has shown deficits in the quadriceps in patients with RA (151) and DM-PM (155). Patients with RA, AS, SLE, JIA, DM, and JDM have been found to have decreased aerobic capacity (156–161).

The biomechanical advantage of joints is compromised by weak muscles. Normally, muscles function to provide postural stability and distribute forces of impact and stress across joints during activity. Normal joint function requires that muscles contract and relax synchronously. Atrophic muscles around joints do not coordinate well and are deficient in both static endurance and strength. There is decreased tone and increased spasm in muscle surrounding arthritic joints, resulting in less coordinated motion of the joint (146). Exercise programs for patients with arthritis have been shown to produce a variety of benefits that include:

- Increase and maintain ROM (162).
- Reeducate and strengthen muscles (163).
- Increase static and dynamic endurance (156,164–166).
- Decrease the number of swollen joints (166).
- Enable joints to function better biomechanically (146).
- Increase locomotor ability (165,167).
- Increase bone density (165).
- Decrease pain (168).
- Increase the patient's overall function and well-being (168–170).
- Decrease inflammation (171–173).
- Increase aerobic capacity (159,169,174,175).
- Reduce body weight (176).
- Limit rheumatoid cachexia (177,178).

Exercise prescriptions should be designed to improve function that patients value. Once these goals are set, limits need to be established that preserve joint function and do not unduly fatigue inflamed muscle and joint structures. Exercise should be performed with proper joint support, after

reduction of joint effusion is accomplished, and attention should be given to the level of aerobic capacity (158). Patients with collagen diseases often have cardiac abnormalities, which should be evaluated before initiating an exercise program and on an intermittent basis while on a maintenance exercise program (179). Exercise programs for arthritis patients should specify whether the exercise should focus on aerobic activities, strengthening, and/or be aimed at building muscle endurance. Prescriptions should specify the muscles that need strengthening; the type, intensity, duration, and frequency of exercise to be used; and the specific precautions (158). It is helpful and generally felt to improve compliance if the patient is provided with a written exercise program and verbal directions if the program is to be performed at home. Patients who exercise as part of a group or with a partner are more likely to adhere to a given program. The patient or family, or both, should be told the purpose of the exercises (see Table 40-9).

An exercise program should be progressive. It should start with relieving pain of the involved joints with appropriate modalities, and/or pain medications. Once comfortable, a combination of stretching, strengthening, and fitness training should be initiated in a progressive manner. A program that shows results in terms of functional activity is best. Isometric exercise is usually the initial approach, with the addition of an isotonic exercise program for muscle endurance and for strengthening if joints permit. Isotonic low-resistive and low-weight progressive resistive exercise, as well as low-force isokinetic exercise can be used without joint damage. Incorporating exercise into recreational activities may be the treatment of choice for the patient because of its inherent appeal and the fact that it is done outside of a medical setting. Depending on joint integrity, a variety of options (i.e., gardening, swimming, mall walking, low-impact dancing, table tennis) are safe and effective for those with RDs (147).

### Passive Exercise

Passive exercise is beneficial for patients with severe muscle weakness due to PM or neuropathic disease associated with stroke, peripheral neuropathy, and vasculitis. Patients with acute joint flares should passively or actively move the acute joint through the tolerable range once or twice a day, to prevent motion loss. Caution should be applied as passive exercise may also increase intra-articular pressure in the presence of joint effusion and has been associated with rupture of the joint capsule with large effusions (147).

### Active Exercise

Active resistive exercise uses three types of muscle contraction:

1. Isometric or static contraction, which is highly suited for arthritis patients with mechanically deranged joints.
2. Isotonic or dynamic contraction, which is most suited for patients without acutely inflamed or biomechanically deranged joints, because it stresses the joint throughout its ROM.
3. Isokinetic dynamic contraction, which in most cases is not recommended for arthritis patients.

### **Strengthening Exercise**

Strengthening of a muscle in arthritis patients may be achieved via isometric, isotonic, or isokinetic exercise. The degree of inflammation and disease stage should be evaluated before making an exercise choice. Isometric (i.e., static) exercise is ideally suited for restoring and maintaining strength in patients with muscle atrophy from RDs and steroids, and for the recovery phase of DM-PM, and for patients with significantly biomechanically compromised joints. Machover and Sapecky demonstrated a significant increase (27%) in quadriceps strength in patients with RA on an isometric strengthening program (180). This program consisted of three daily maximal contractions held for 6 seconds, with 20 seconds of rest between each. The knee was in 90 degrees of flexion. The opposite quadriceps had a cross-over effect with a 17% increase in strength. A similar program for a PM patient increased strength (1). To decrease force across a joint, a less than maximal contraction should be used. To effect strengthening this should not be less than two thirds of the maximal contraction. The patient should be instructed how to do this.

An advantage of isometrics is that muscle tension can be generated with minimal joint stress. Pain has been reported with maximal contraction. One study of adults by Gnootveld et al. indicates that isometric quadriceps exercise of inflamed knee joints in RA yields increased oxidative damage to hyaluronate and glucose, determined by analyzing synovial fluid 1 hour following exercise (181). Therefore, isometric exercise in an inflamed joint is not recommended. However, pediatric rheumatologists often recommend a few isometric contractions a day in children because loss of strength can be rapid around inflamed joints.

With isometric exercise, muscle strength is only achieved at the angle at which the muscle is trained. With isotonic, strength is achieved throughout the range. In addition, strength obtained by isometric training is not fully transferable to isotonic tasks. Therefore, the addition of isotonic exercise to the arthritic program is warranted where appropriate. DeLorme progressive resistive exercises with high loads and low repetitions build strength but put considerable stress across joints. A low-load resistive muscle training program in functional class II and III RA (12-week circuit weight bearing with light loads/high repetitions three times a week) resulted in significant improvement in self-reported joint count, the HAQ, grip strength, and knee extension strength (163). A 6-week high-intensity, progressive resistive strength training program in well-controlled RA patients resulted in significant improvements in strength, pain, and fatigue without exacerbating disease activity or joint pain (182). A recent study of moderate dynamic resistive exercise (with loads of 50% to 70% of repetition maximum) twice a week along with recreational activities showed a significant improvement in strength, disease activity, and walking speed. Bone mineral density (BMD) of the spine was not significantly increased (165). A comparison study of high-intensity aerobic bike exercise (70% to 85% of age-predicted heart rate) combined with full-weight-bearing exercises versus three combined

low-intensity strengthening programs (group, individual, or home-based ROM and isometric) resulted in significant increases in aerobic capacity, muscle strength, and ROM that differed significantly from these changes in the other three groups (162). Strength increases were seen in PM patients on an isotonic resistive machine program (183) and home program (184).

Dynamic isotonic high-resistive exercise has the potential of exacerbating inflammation in general, which can increase muscle fatigue and joint pain and secondarily decreases joint ROM. Progressive resistive high-intensity isotonic exercise and isokinetic exercise are not recommended for those with arthritis. Moderate-intensity isotonic programs can be used in selected cases. Joints should be nonactive and biomechanically intact. Strength gains with isokinetic exercise do not exceed those obtained with low-weight, isotonic strengthening programs, and equipment is expensive and only available in a clinic (185).

Isokinetic testing of strength has been done in a 1990 study of RA patients with mild joint disease (186), and in PM patients (187) without deleterious effects. An isokinetic strengthening program used in RA patients increased strength. Complications included several joint flares and a ruptured Baker cyst (188). A 1994 study on a small group of RA patients showed that isokinetic strength training at four speeds for 3 weeks significantly increased strength without joint flares (189). A 1999 study revealed increased knee flexion torques at 60 and 90 degrees/second in RA patients on a knee flexion/extensor training program. The patients had nonacute RA (190). An isokinetic program with medium (120 degrees/seconds) velocity is most likely used in RA patients. Low velocities (30 to 90 degrees/seconds) produce high torque around joints and are best avoided. Isokinetic exercise should not be used in arthritic patients with joint effusion, Baker cyst, ligamentous laxity, acute joints, or joint replacements. A study of isokinetic exercise in six PM-DM patients demonstrated a significant increase in strength without significant creatine phosphokinase (CPK) increases (191). See Table 40-14 for specific exercise regimens.

### **Endurance**

Patients with systemic RD have an overall limited endurance, and their ability to continue static or dynamic tasks is impaired. Endurance exercise can lead to an increased functional level in RA patients (192,193). In 1981, Nordemar described RA patients who were trained for 4 to 8 years on a bicycle ergometer at home and a self-suited exercise program consisting of jogging, skiing, swimming, and cycling (194). He found improved ADL performance in the exercised group as well as less progression of X-ray changes in arthritis, more improvement in hamstring strength, and less sick leave (195). Harkcom et al. (196) also reported benefit from aerobic exercise in RA patients. Minor et al. showed that aerobic exercises increase aerobic capacity in both RA and OA patients. Decreased joint counts for pain and swelling also have been associated with aerobic programs for RA patients (166,170,182). Exercise programs using different combinations of ROM, strengthening exercises, and aerobic exercises on land and in the pool have been beneficial in RA (147).

TABLE 40.14 Exercise Summary Chart

Type of Exercise	Study	Patient Population	Duration	Frequency	Intensity	Outcome
Strengthening (progressive resistive)	Rail et al. (182)	8 well-controlled RA 8 controls	12 wk	2×/wk	80% of maximum adjusted upward weekly	Significant increase in strength with decreased pain and fatigue
Moderate resistive (controls—ROM and stretch)	Hakkinen et al. (183)	35 recent onset RA >2 y RCS 35 controls	2 y	2×/wk	Loads of 50%–70% rep max (2 sets with 8–12 reps; 45 min each person)	Significant increase (19%–59%) in strength with decreased disease activity (HAQ) with increase in walk speed
Progressive resistive (machine)	Spector et al. (185)	5 PM (IBM) UCS	12 wk	3×/wk	3 sets (10, 15, and 20 reps) 90-s rest each set	Significant torque increase in lower-extremity muscles (except RT quad)
Isokinetic (Lido) (controls—no exercise)	Leventhal et al. (188)	10 RA with mild knee involvement 10 controls	6 wk	3×/wk	120° s 90° s 60° s	Significant increase in torque at 120, 90, and 60 degrees/second in subjects with significant increase in total work
Low load resistive weight-bearing exercise	Kumati Reddy et al. (163) 2-y controls	JIA (class II–III) RCS	12 wk	3×/wk	PRE (3–4) 12–15 reps set in 30 s with 30-s rest period between sets	Significant increase in extension, strength/(0.03) decreased joint count, decreased HAQ score; significant decrease in number of painful joints
Isotonic resistive plus walking	Alexanderson et al. (184)	11 active PM UC	12 wk	5×/wk	27–30-min session with 1–3-lb weights High to moderate muscle function (0.25–2 kg) weights: low muscle function (anti-gravity) ten reps per muscle group, total 15 min Alternating every 2 wk ROM with isokinetic exercise	Significantly improved function by (function index for myositis) SF-36  60% increase in isokinetic peak torque
Isokinetic and ROM	Escalante et al. (191) UC	5 PM (active) No controls	2–7 mo	2×/wk	70% increase of max speed four sets of five reps (1-min rest after each set) controls not stated	Increase in knee flexion torque at 60 and 90 degrees; significant decrease in pain (P.O.C.) increase flexion (HAQ)
Isokinetic knee extension/flexion	McMeeken et al. (190) RC	18 nonacute RA 18 controls RCS	6 wk	3×/wk	Concentric/eccentric contraction all MAS or muscle group 80% repetition; max two sets of 8 reps each	Significant strength increase; decrease in pain; no increase in disease activity or joint pain
Progressive resistive (high intensity) isokinetic machines	Rall et al. (182)	Exercise group 8 RA (well controlled) 8 healthy young 8 healthy elderly CS	12 wk	2×/wk		

(continued)

TABLE 40.14 Exercise Summary Chart (continued)

Type of Exercise	Study	Patient Population	Duration	Frequency	Intensity	Outcome
Aerobic Walk aquatics Controls—ROM	Minor et al. (168)	40 RA 40 OA (controls) RCS	12 wk	3×/wk	1 h (30 min aerobic and warm-up and cool-down) at 60%–80% $\dot{V}O_2$ max	Significant increase in aerobic capacity and walk time; decreased anxiety and depression
Stationary bicycle and step aerobics	Wiesinger et al. (175)	14 PM (controls) RCS	6 wk	2×/wk (first wk) 4×/wk (next 4 wk)	1 h 60% max heart rate (5-min warm-up, 5-min cool-down)	Significant increase in ADL and $\dot{V}O_2$ max in study group; no increase in disease activity
Subject	Van den Ende et al. (197)	25 RA each of four groups	12 wk	High intensity 3×/wk	High intensity—70%–80% max heart rate—1 h	Intensive aerobic training with significant increase in aerobic capacity; strength and ROM no increase in disease activity; loss of effect 12 wk postexercise
Group 1 Full weight-bearing stationary bike		RCS		Low intensity 2×/wk	Low vs. high intensity group, individual, and home; isometrics/ROM in 1 h	
Group 2 ROM/isometrics in a group						
Group 3 ROM/isometrics						
Group 4 ROM/isometrics at home						
Dance-based aerobics	Novreau et al. (211)	19 RA (class I–II) 10 controls	12 wk	2×/wk	50% max heart rate (first 3 wk) 70% max heart rate (9 wk); (10-min warm-ups and 15–30 aerobics)	Study group significant increase in aerobic capacity and walk time and peak torque
Dance-based aerobic program	Novreau et al. (212)	10 RA (class II–III) UCS	8 wk	2×/wk	50% max heart rate (first 3 wk) 60%–70% max heart rate (last 2 wk) warm-up 10-min aerobic exercise (at 6 wk 25-min aerobic exercise)	No significant group aerobic capacity gain (four of ten subjects had 10%–20% aerobic gain); significant decrease in anxiety and depression; significant decrease in swollen joints; significant increase in walking, speech

Low-impact aerobic dance	Moffet et al. (167)	10 RA (class III) UCS		50% $\text{VO}_2$ max (first 3 wk) 60%–70% max $\text{VO}_2$ rest of program	Moderate intensity aerobic 7-min warm-up with 10-min aerobic and 2-min walk each of program up to 20-min aerobic recovery and cool-down (8 min)	Significant improvements in isomotor ability
Aerobic (supervised) walking (controls—no training)	DeCarvalho et al. (304)	41 SLE (training) 19 SLE (controls) (SLEDAI scores eight or above)	12 wk	3×/wk (one supervised session two at home sessions)	1 h (40 min aerobic walk at HR 10 min warm-up 10 min cool-down)	Significant increase in $\text{VO}_2$ max ( $P \leq 0.0001$ ) Inter-group comparison: Significant difference in $\text{VO}_2$ max ( $P = 0.01$ ) and aerobic threshold ( $P = 0.0001$ ) favoring aerobic group Significant improvement in Back ( $P \leq 0.001$ ) and HAQ ( $P = <0.01$ ) Significant improvement in CHAQ Both groups ( $P \leq 0.0001$ ) (no inter-group difference)
Aerobic (high intensity) Dance and cardio-karate Experimental group I Qigong (control group II) Combined	Singh-Grewal et al. (352)	40 JIA each of two groups (stable active) RCS	12 wk	3×/wk (one supervised—two at home sessions)	50 minute High Intensity Group 1 (30 min 75% MHR and 10 min warm-up and 10 min cool-down)	
Mobilization Strengthening Stretching Chest	Karapolat et al. Van den Ende in a 2000 Cochrane database study reviewed dynamic aerobic training and its effect on improving joint mobility, muscle strength, aerobic capacity, and function in RA patients. Negative effects such as increased pain, disease activity, and radiologic progression were also assessed. Selection criteria included randomized control trials on the effect of dynamic exercise therapy, an exercise program of at least 60% maximal heart rate for 20 minutes at least two times a week for 6 weeks. Only six of 30 controlled trials met criteria. It was concluded that dynamic exercise has a positive effect on physical capacity as measured by aerobic capacity and strength. Further research is needed on the positive effect on functional ability and radiologic progression (197). A RCT of dynamic training revealed RA women on low-dose steroid on a dynamic weight-bearing program showed positive effects on physical function and fitness level, and BMD with no disease exacerbation (198). Another trial reports the effect of intensive exercise in patients with active RA (161). A 2008 Cochrane database review summarizes dynamic exercise effect in RA (199).

Wiesinger reported improved physical fitness and muscle strength with short-term 6 week and long-term aerobic programs in DM-PM (175,186). Children with JIA can improve their aerobic endurance with a weight-bearing fitness program without disease exacerbation (171). SLE patients have been shown to increase their aerobic capacity by 20% on a bike aerobic program (156). A 12-week, 3×/week multimodal exercise program (aerobic stretching and pulmonary exercises) versus a medication only control group showed significant improvement in spinal mobility, work capacity, and chest expansion in the exercise group (200).

Bone mineralization is thought to be partially dependent on muscle contraction. Exercise has been shown to have a positive effect on bone mineralization in postmenopausal women (201). Patients with RD develop osteopenia from disuse, medication, and calcium and collagen metabolism abnormalities. Most studies that support the positive effects of exercise in these areas cite the use of isotonic and some resistive exercises. Sinaki and Grubbs showed in a study that back extensor exercise can increase spinal bone density in postmenopausal women (202). This type of exercise may be useful for RD patients.

### ***Stretching Exercises***

Stretching may be used to prevent contractures and maintain or restore ROM by breaking capsular adhesions. These exercises must be graded according to the degree of inflammation, pain present, and pain tolerance of the patient. Heat may be used to increase collagen extensibility and cold to decrease pain before stretching exercises. Stretching to preserve or increase ROM should not be performed if there is acute inflammation, because it may increase it.

Active-assistive stretching can be used for maintaining or increasing ROM when the problem is subacute and pain is decreased. The patient initiates muscle contraction, and the therapist or an assistive device serves as an aid. Forceful stretching should be avoided in the presence of a large joint effusion because capsular rupture may occur.

Active stretching is performed in the absence of pain and inflammation to maintain ROM. It may be facilitated by the use of pulleys. Active stretching exercises in a pool are excellent. Devices may be needed to facilitate stretching for hip flexion contractures in JIA and knee flexion contractures in RA. Passive stretching has been found useful in increasing hip and shoulder motion in AS patients (203) (see Table 40-14).

### ***Aquatic Therapy***

The benefits of performing exercise in a pool include elimination of gravity and the positive effect of water buoyancy, which may result in decreased joint compression and pain (204,205). This may further result in increased muscle relaxation. In addition, a greater level of aerobic exercise may be tolerated in the water than on land. Therefore, therapeutic pool therapy may be most useful for those with moderate to severe arthritis, with recent joint replacement, with AS, and with any cardiopulmonary compromise.

Specifically, Danneskiold-Samsøe et al. have shown in a study on RA patients that isometric and isokinetic quadriceps strength can be increased by 38% and 16%, respectively, by adhering to a 2-month pool exercise program when compared with pretreatment values. A significant increase in aerobic capacity also can be obtained in RA patients on a pool program (206). AS patients with reduced vital capacity have been shown to be capable of undergoing pool therapy programs without untoward effect (207). In a RCT it was demonstrated that combined spa-exercise therapy is effective in patients with AS (208). Exercise tolerance appears to be related to pulmonary function in these patients (209).

### ***Recreational Exercise***

Patients with RDs often want to participate in recreational exercise programs (170). Care must be taken to advise the patient which activities or programs would be beneficial for him or her, and to relate the use of recreational exercise to the condition of the joints (i.e., inflamed, subacute, chronic mechanical derangement problems). In exercise gyms, the use of preset rate-limited devices at high torque speeds of muscle contraction against high resistive forces on machines should be avoided. Light weights (3 lb or less) and minimal repetitions (ten or less) on isotonic machines are permitted for patients with RA with no inflammation, minimal x-ray changes, and no ligamentous laxity. If isotonic weight lifting is performed, it generally should be with light weights (1 to 3 lb), and ten repetitions. A short arc of motion can be used to decrease joint pain. Swimming is an excellent form of isotonic exercise for arthritis patients because gravity is eliminated and ROM of the joints is less painful. ROM and stretching exercises, and pool jogging or walking are good. Local chapters of the AF have aquatic courses for arthritis patients and often make heated pools available. The Young Men's Christian Association also has special pool exercise programs. Adaptive devices and special handgrips are available to help patients in specific sports (e.g., table tennis, golf, gardening, and bowling).

### **Dance**

Dance has become a popular recreational activity for patients with arthritis. It can help increase joint motion, muscle strength, and aerobic capacity. Van Deusen and Harlowe describe the efficacy of a ROM dance program for adults with RA (210). Other, more formal and therapeutic dance programs, such as Educize, have shown increased strength, flexibility, and aerobic capacity along with decreased joint pain and depression (193). Formal dance-based aerobic programs for RA have shown positive effects: (a) changes in fatigue, tension, and aerobic capacity (211); (b) positive changes in fatigue, depression, and anxiety with increased aerobic capacity in some patients with class III disease (212); and (c) significantly improved locomotor ability by gait test in class III RA (213).

### **Jogging**

Dry land jogging, which involves repetitive joint motion and offers little chance for increase in strength, is not recommended if arthritis of the knee, hip, or ankle is present.

It is a good rule that a patient should be made as strong as possible by isometrics, and strength and local muscle endurance increased by light isotonic exercises, before recreational exercise is begun. Indications of excess therapeutic and recreational exercise include postexercise pain at two or more hours, undue fatigue, increased weakness, decreased ROM, and joint swelling. If these occur, the program should be adjusted.

### **Treatment with Heat and Cold Modalities**

Therapeutic heat can be applied with a number of devices and techniques. The effect on the tissue, location, surface area, depth of the tissue, and acuteness or chronicity of the arthritis must be considered in the selection of modalities. Most investigations on the use of superficial and deep heat and cold modalities have produced conflicting data. Recent formal literature reviews utilizing the Cochrane Databases and specific study selection criteria have been done for treating RA with thermotherapy (heat and cold) (214), balneotherapy (bathing/spa therapy) (215), and therapeutic ultrasound (US) (216). Only RCTs were selected for data analysis. Problems with poor methodological quality and inadequate statistical analysis and outcome measures often hindered pooling data and made conclusions about treatment efficacy difficult. The general conclusions from the thermotherapy reviews indicate no effect on objective measures of disease activity (inflammation, pain, x-ray measured joint destruction) of either ice versus control or heat versus control. Ninety-four percent of patients reported they preferred heat therapy to no therapy. There was no difference in patient preference for heat or cold, and no harmful side effects were noted (213). The balneotherapy review indicates ten studies report positive benefits, but the findings should be viewed with caution because of methodological flaws (215). The review on US suggested that ultrasound alone on the hand increases grip strength. It did not conclude that the combination of US with exercise, faradic current, or wax therapy was beneficial (216).

Recent data have helped clarify some dilemmas in this area. Therefore, we have some data (both human and animal)

of the effects of these modalities on pain relief and disease activity. With the use of these data and clinical observation, recommendations can be made as to the appropriate use of heat and cold alone or in combination with other modalities for acute or chronic arthritis.

### **Heat**

Superficial heat has been used for hundreds of years for pain relief in patients with arthritis. Patients report that warm baths, heated pools, hot packs, and warm mineral springs provide relief of joint pain and stiffness. Studies (217) indicate that superficial heat applied to patients with arthritis increases both skin and joint temperature in inflammatory arthritis. Painful stimuli, apprehension, alarm, or smoking lowers skin temperature and elevates knee joint temperature, as do active and passive exercise.

When joint temperature is increased from 30.5°C to 36°C, as it is in active RA, collagenase found in rheumatoid synovium is four times as active, resulting in lysis of cartilage (218). Increasing joint temperatures increases the metabolic rate and may increase inflammation and joint destruction (218). Mainardi et al. (219) found no increase and no decrease in joint destruction and inflammatory activity in the hand in RA with the use of superficial heat.

Heat affects the viscoelastic properties of collagen. As tension is applied, stretch is affected, and an increase of creep (i.e., the plastic stretch of ligamentous structures placed under tension) occurs. Heat may enhance the efficacy of stretching if applied to appropriately chosen joints.

Both superficial and deep heat can raise the threshold for pain, producing sedation and analgesia by acting on free nerve endings of both peripheral nerves and  $\gamma$  fibers of muscle spindles.

### **Cold**

Cold modalities such as air or ice decrease skin, muscle, and joint temperature in arthritis patients (217). The application of cold to rheumatoid joints may, therefore, inhibit collagenase activity in the synovium. Some clinical studies have shown greater and more prolonged relief of pain with ice than deep or superficial heat in patients with RA (220). Other investigations found the increase of knee joint ROM to be the same with either ice or superficial heat applied daily for 5 days, with a 9-day interval between the two treatments (221).

Cold decreases muscle spasticity by direct action on the muscle spindle activity (222) and raises the pain threshold. Cold should not be used in patients with Raynaud's phenomenon, cold hypersensitivity, cryoglobulinemia, or paroxysmal cold hemoglobinuria. The abrupt application of cold causes discomfort and produces a stressful response.

In treating the acutely inflamed or subacute joint, the goal is pain relief. One is careful not to use interventions that may increase the metabolic rate and secondarily increase inflammation. The use of cold seems most logical because it can decrease the pain threshold, can relax surrounding spastic muscles, and is associated with decreased joint temperature, collagenase, and cell count in the joint fluid (223).

**FIGURE 40-3.** Night resting splint for hand and wrist immobilization.

Later in the subacute period, when inflammatory pain is subsiding and stiffness is present, and the patient may have lost some ROM, either cold or superficial heat is appropriate and the patient should decide based on what is most convenient, economical, and effective.

### Orthotics

Splints and orthotics are used to unweight joints, stabilize joints, decrease joint motion, support joints in a position of maximal function, and increase joint motion (i.e., dynamic splint). Splints may be prefabricated but are best when molded to fit the individual patient.

### Upper Extremities

Orthotics for the upper extremities are mainly confined to the wrist and hand and include resting splints, functional wrist splints, thumb post splints, ring splints, and dynamic splints. Resting splints immobilize the hand and wrist and are used at night for patients with active RA, carpal tunnel syndrome,

**FIGURE 40-4.** Functional wrist splint, providing wrist support and allowing finger movement.

**FIGURE 40-5.** Silver ring splints, used for reducing Swan neck deformity.

or extensor tendinitis (Fig. 40-3). The role of splints in preventing deformity in RA has not yet been scientifically proven. The clinical recommendation is to use both resting and functional splints in early RA. In JIA they probably help in delaying ulnar deviation and in reducing pain, synovitis, and edema. Functional wrist splints extend to the mid-palmar crease, permit finger function, block wrist flexion, and are used for activities during periods of inflammation. They provide wrist and ligament support. A 2008 study using prefabricated working wrist splints revealed a 32% decrease in wrist pain (control group had a 17% increase in pain) (224). A functional thumb postsplint may be used to relieve carpal-metacarpal (CMC) and IP pain associated with OA. The same type of splint with a longer wrist extension is useful for de Quervain extensor tendinitis of the thumb. A functional wrist cock-up splint can help relieve pain in carpal tunnel syndrome (Fig. 40-4).

Small ring splints (e.g., Bunnell orthoses, boutonniere orthoses) can reduce swan neck or boutonniere deformity. Cosmetic splints made of silver or gold and highlighted with semiprecious stones are available (Fig. 40-5).

For patients who have had MCP replacements or who have a radial nerve neuropraxia, a dynamic outrigger splint pulls the fingers into extension, from which patients must actively work to pull into flexion (Fig. 40-6). They provide gentle stretch through limited range while supporting the wrist and MCP joints. Splints that realign digits to help reduce ulnar deviation are also available (Fig. 40-7).

Elbow orthotics are rarely used. They may be useful in children with JIA and PM. Resting night splints may help to contain the advancement of an elbow flexion contracture. Braces with dial locks are used to increase extension during the day.

Compliance with splints has been assessed in a number of studies. Compliance is best when family members expect the patient to be compliant and when the patient uses splints to relieve pain. Cosmesis is a major factor for nonuse, as is fear of discrimination in the workplace.

**FIGURE 40-6.** Extension outrigger and dynamic splint that provide extension assist and phalangeal alignment. Often used postoperatively following MCP arthroplasty or with subluxed MCPs, and weak extensor function.

### Lower Extremities

The most useful orthotics in arthritis are those for the foot and ankle. Those for the knee have been less successful, and there are none generally used for the hip. The advances in lighter materials for orthotics assist in reducing energy consumption with their use.

**Foot/ankle.** Excess pronation at the subtalar joint, loss of the medial arch, and subtalar movement commonly seen in RA can cause pain, contribute to tarsal tunnel syndrome, and cause strain on the knee and hip. Control of pronation by bringing the calcaneus perpendicular to the floor often relieves pain and helps to balance the weight-bearing column (Figs. 40-8 and 40-9). The first step toward control is to fit the patient with a shoe with a good heel counter and a soft or rigid orthotic insert lined with Spenco (AliMed, Dedham, MA). The sole should not be too soft. This will minimize the flotation effect on heel-strike and stance during gait and decrease

**FIGURE 40-8.** Calcaneoeversion R greater than L.

stress, hypermobility, or instability at the ankle or a higher joint level. If pronation is not controlled by a shoe, a hind-foot orthotic has been shown to improve gait and reduce pain (Fig. 40-10). A beveled heel that makes a 20-degree angle with the floor can decrease ankle motion and pain. For the very painful or arthritically involved RA ankle, a short-leg patellar tendon-bearing orthosis that shifts weight away from the ankle to the patellar tendon is useful. Plantar fasciitis may be relieved with a cup insert or an insert with a depression in the area of the tender fascia.

Appropriate wide toe-box shoes should be used to accommodate a wide forefoot, cocked toes, and hallux valgus seen in RA or JIA, as well as the hallux valgus deformity seen in OA. A soft insert is added, as are metatarsal reliefs, whether in the form of a cookie inside the shoe or an external bar on the sole of the shoe. We prefer the former because we believe it to be safer. A rocker bottom shoe can facilitate rollover in the presence of a painful ankle. Sometimes it is best coupled with a stirrup type brace to provide subtalar support (Fig. 40-11).

**FIGURE 40-7.** Ulnar deviation splint to realign phalanges and provide a block to metacarpal bone deviation.

**FIGURE 40-9.** Correction of calcaneoeversion, using a total-contact orthotic with medial posting and arch support.

**FIGURE 40-10.** Comparison between standard ankle foot orthosis (A) and hindfoot orthosis (B) designed to control subtalar motion.

**Knee.** Braces for the knee may be used for pain relief, instability caused by ligamentous laxity, significant quadriceps weakness, or excess recurvatum. A useful brace for quadriceps weakness is a double upright Klenzak (Pel Supply, Cleveland, OH) set at 5-degree plantar flexion at the ankle to put the knee in extension during heel-strike and stance. The Klenzak can be used for a unilateral problem or for the weaker side when the problem is bilateral, as in PM. Success can also be achieved with a plastic molded ankle-foot arthrosis (AFO) cast in 5-degree plantar flexion with a small added 3/8-in. heel incorporated into the orthosis, provided the patient is not overweight. A Lenox Hill orthosis (3M, Long Island, NY) may

**FIGURE 40-11.** Combination of use of stirrup-like hindfoot support with adapted athletic shoe demonstrating a rocker sole to assist in forefoot pushoff.

be used to control mediolateral or rotational instability. These braces are rarely used in RA but are used for younger athletic individuals.

A knee, ankle, foot orthosis (KAFO) with ischial weight bearing and dial lock at the knee can be used to reduce knee pressure and may be adjusted to relieve medial or lateral compartmental stresses in OA or RA. This orthosis is difficult to fit with severe valgus deformities and in the obese patient. Compliance in the use of KAFOs is poor.

Smaller knee orthoses, such as hinged orthoses, the Swedish knee cage, or Lerhman orthoses (Pel Supply, Cleveland, OH), may be used to help control sagittal and frontal knee plane motion. A knee orthosis to help prevent dislocation of the patella is available and often effective. A shoe with a beveled heel at 20 degrees also decreases knee flexion and promotes a more stable extended knee. Orthoses with a dial lock turned 1 or 2 degrees daily can be used to reduce knee flexion contracture. Elasticized knee supports may help control swelling and often provide patients with a sense of control of the quadriceps.

### Spinal Orthoses

Spinal orthoses are used primarily to relieve pain, limit motion, or support an unstable spine. A lumbar spinal orthosis or thoracic orthosis with mold and form insert will often relieve a painful back due to compression fracture or disc disease. This type of orthosis may reduce lordosis, reinforce abdominal muscles, and unload the spine. For thoracic compression fractures prone to gibbous deformity or an unstable lumbar or thoracic spine, a Jewett orthosis (Florida Brace, Winter Park, FL) or a molded polypropylene body jacket is required. A lumbosacral corset does not limit motion but provides some abdominal support and relieves painful lower lumbar musculature.

The cervical spine is involved in RA, OA, JIA, and spondyloarthropathies. Various collars provide different levels of support. A soft cervical collar only minimally limits motion but provides some pain relief. A Philadelphia collar (Pel Supply, Cleveland, OH) offers slightly more support and some limitation of extension. A two-poster, four-poster, or sternooccipital mandibular immobilizer (SOMI) brace substantially limits flexion and extension, particularly at C1, at C2, and also at C4 and C6. A halo is needed to completely control C1, C2 instability.

### Assistive Devices and Adaptive Aids

Assistive devices and adaptive aids compensate for limited ROM and pain, and help promote independence and lesser impairment, and disability for arthritic patients. To help ensure patient acceptance, the appliance should be affordable, be easy to use, and improve patient function.

Ambulation and transfer skills are extremely important for persons with arthritis, and gait aids and devices may also be needed.

### Gait Aids

If joint pain is a problem, secondary to loss of cartilage, effusion, or active synovitis, the painful joint needs to be unloaded.

Weight reduction is encouraged, because a 1-kg weight loss results in a 3- to 4-kg decrease in load across the hip joint. A straight cane when used properly unloads the limb by 25% (2), which is good for balance but is not as efficient in unloading the limb as compared to a forearm crutch. The elbow should be in 30 degrees of flexion when such a device is in use.

Custom handgrip pieces can be made by making a mold of the patient's hand in a functional position of weight bearing, or commercially made hand pieces on canes can be used. Platform crutches distribute weight on the forearm, reducing the need for wrist extension and eliminating weight-bearing forces through the wrist and hand. Forearm attachments for walkers and wheelchairs are available.

For significant loss of strength or endurance, a small, lightweight wheelchair is recommended. There are also small motorized scooters, such as the sporty Amigo Chair (Amigo Mobility Intl. Inc., Bridgeport, MI); however, power wheelchairs will offer more seating options for those with spinal/pelvic involvement.

### ***Adaptive Devices for Transfer***

Chronic hip or knee pain, limited motion, and proximal muscle weakness make transfers from low-level chairs, toilets, and beds difficult. Upper extremities may be needed for pushoff, but when these are incapacitated by RA, such simple motion becomes impossible. Independence in making transfers can be restored by elevating the seat with a cushion or using a levered seat or placing 3- or 4-in. blocks under each leg of chairs, tables, and beds. Chairs with elevating motorized seats, elevated toilet seats, and clamp-on tub seats are also helpful.

Transfers in and out of the car are facilitated by the use of an extra-thick seat cushion, levered seat, or twist-about plastic disk and a mounted grab bar to increase leverage. In the car, use of the side, rearview, and wide-angle mirrors for patients with limited cervical ROM as a result of spondyloarthropathies becomes essential. A spinner bar for the steering wheel and a large-handled door opener and ignition piece are adaptations for the patient with significant hand problems. Patients with back pain benefit from a firm seat and back cushion, such as a PCP Champion Sacro cushion (OTC Professional Appliances, Ripley, OH). Those with neck pain need adjustable neck supports or pillows.

### ***Self-care***

Dressing, undressing, and other daily self-care activities can be time- and energy-consuming tasks for those with RA, SLE, and PM. Adaptive and self-care aids such as long-handled reachers, shoehorns, elastic shoelaces, long-handled sponges, brushes and toothbrushes, Stirex scissors (North Coast Medical, San Jose, CA), button hooks, zipper hooks, toilet paper holders, and large-handled items are all helpful devices that also conserve energy. Clothing made with elastic and Velcro is easier to don than that with buttons and hooks. Wrinkle-resistant fabrics that do not require ironing and lightweight fabrics and wools (e.g., mohair, alpaca) are useful. Large buttons and partial zippering before putting on the garment may facili-

tate dressing, as will stretch straps and waists, garments with large raglan sleeves, and those with smooth linings. Capes, ponchos, and down jackets are easy to put on, are warm, and lightweight.

### ***Devices in the Kitchen***

Useful kitchen devices include food processors, long-handled reachers, built-up handles on utensils, electric knives, and vegetable peelers, mounted wedge-shaped jar openers, and lightweight aluminum pans. Lining pans with aluminum foil saves scrubbing. Bringing together items involved in a work area (e.g., kitchen stove, work area, sink, refrigerator) is helpful. A microwave oven cuts down on food preparation time. A kitchen cart loaded with often-used utensils cuts down on walking. These are all excellent examples of tools for work simplification and energy conservation.

### ***Environmental Design***

Slopes, stairs with deep steps, high curbs, and buses or cars may be difficult to negotiate for someone with disease of the hips and knees. Appropriate placement of steps, lowered curbs, suitably graded inclines, and ramps are helpful. Buses that kneel to accept passengers are available in many communities. Indoors, thick carpets increase friction and are difficult to walk on or negotiate in a wheelchair. In the bathroom, guard rails are best for safety. The bathtub should have nonskid strips or an entire nonskid surface. A wheeling shower with a wall seat is excellent for wheelchair use. Door openings should be wide enough to accept a wheelchair. Chest-high storage cabinets and waist-high work surfaces are best; special door handles are available. For those patients in wheelchairs, proper positioning of doorknobs, light switches, and kitchen equipment is necessary. Large-handled pencils and eating utensils are helpful. Devices to help with spray cans are available. The AF provides a catalog of available assistive devices ([www.arthritis.org](http://www.arthritis.org)).

### ***Education***

One of the most important aspects of care for patients with inflammatory disease, and perhaps all chronic illness, is a good rapport between physician and patient. This begins with clear communication between patient and health care providers so that patients can be assisted in habilitation or adjustment to the chronic disease process. In addition, educational groups consisting of arthritis patients who gather to hear experts in the field and talk about aspects of medical and rehabilitative management are very informational and supportive. They also provide a social context for coping with medical and psychosocial problems. Local hospitals, the YMCA, and the AF and other disease foundations and local interest groups offer such group activities.

It has been thought that patients with RA, and chronic disease in general, have had significant disability based on inactivity and lack of motivation. Approaches to solving this problem and promoting better patient function have included techniques to empower patients and to promote self-efficacy, thereby overcoming learned helplessness (225).

Educational intervention, using disease self-management programs, has been employed in the treatment of RA, SLE, AS, and fibromyalgia. These have reduced pain, improved function, and delayed the onset of disability. They are also under-used (226–228). Studies show that information is helpful in empowering patients and it often helps to relieve anxiety. However, educational interventions that only promote increased knowledge have little impact on disease activity and behavior. Educational models that establish approaches to problem solving, support groups, and healthy lifestyle/fitness behaviors are usually more effective in promoting improved function.

Patient education should include a discussion about the natural history of the disease and the likely impact that it will have on lifestyle, job, and leisure activities. Many systemic RDs are chronic and have periods of remission and exacerbation that affect function. Planning activities so that they are done at the optimal time of day, or are broken up into smaller intervals for sustained activity, may permit completion of important activities without undue fatigue.

A full discussion of the impact that medication may have will help alert patients to medication-related problems. For example, corticosteroids may cause muscle atrophy, upset sleep patterns, and alter appearance. These changes may have profound effects on mood, energy, and strength, all of which may influence function.

### **Joint Protection**

It is well known since the observations of Cordery that arthritic patients change their lifestyle and habits to protect their joints and use adaptive strategies and devices that make work easier rather than persist with activity that causes pain (229). However, patients need formal education in this area to learn techniques to reduce force across their joints. Principles of this program include the following: promoting good sitting posture; using adequate back contact, arm rests, and proper height such that the feet touch the floor; changing position frequently to avoid gel phenomenon. Additional examples of ways to protect/preserve joints include: using the largest possible joints to support activity, unweight painful lower-extremity joints, avoid overuse by interrupting sustained activity with rest periods, using adaptive equipment and strategies for efficient use of joints, using splints when limbs need to be supported in functional positions.

### **Energy Conservation**

RD is most often accompanied by fatigue, so conserving energy to maximize function is an important part of the arthritic patient's lifestyle. Some of the mechanisms for conserving energy include the proper orthotics and assistive devices to effect energy-efficient ambulation and hand function, appropriate adaptive aids and clothing, proper environmental design, rest periods throughout the day, maintenance of ROM and strength, and maintenance of proper posture.

Good body posture, whether sitting or standing, balances the weight of the head and limbs on the body framework so

that gravity helps to maintain joint position with minimal muscle activity. Significant changes in posture cause muscles to exert more energy to pull against the force of gravity. For example, standing takes 25% more energy than sitting to perform activities. Ideal posture cannot be maintained unless care is taken to preserve ROM and strength of muscles around the joints.

### **Psychosocial Interventions**

RD has a major impact on the patient's mobility, ADLs, general lifestyle, self-image, family life, sexuality, and work. Stress and depression play major roles in influencing RD patients' reporting of their symptoms and illness.

Two forms of stress play a role in RD: major life events, such as death of a spouse, and persistent negative events (230), such as conflicts with people. The latter stressors can influence immune function and increase global ratings of disease activity in RA (231), increase psychological distress in SLE (232), and increase symptoms in JIA (233).

These studies support the association between stress and symptom flares and indicate that interventions to help coping may be useful. Major patient reactions ranging from denial and repression to depression occur, as do other components of chronic illness, such as anger, bargaining, and acceptance.

Depression is common in RD. It has been reported that 37% of patients with RA have depression (234). Predictors of depression include scores in HAQ, pain intensity (235), and, in women, loss of valued activities (230). A history of depression in RA makes patients vulnerable to higher levels of pain, fatigue, and disability, even if they are not currently depressed, but just in a dysphoric mood (236). The belief that there is a particular personality type prone to developing RA has been dropped. However, premorbid personality is an important determinant of the patient's reaction to illness. Patients with arthritis, in addition to coping with pain, may have to deal with losses in function and physical attractiveness because of the disease and side effects of medication, and they have to deal with the reactions of friends, spouse, and family. Some families adjust well, maintaining good communication, support, and flexibility in family routines. Other families are not able to reorganize and adjust to the needs of a person with arthritis. Psychiatric support for both patient and family is often needed. Group therapy, including discussion about body image, job status, family relationships, and coping mechanisms, is effective and has been used for a variety of arthritic groups.

The unpredictability of systemic disease complicates the coping process. Patients with RD often experience learned helplessness, believing no solutions exist to reduce stressful events, which leads to anxiety, depression, increased pain, decreased activities, and decreased ability to adapt to distress and disability (230). High levels of helplessness are associated with increased pain, depression, and functional impairment in RA and poorer physical health in SLE (237). Self-efficacy in patients with RD may vary for different actions to achieve health-related goals. High self-efficacy for pain is correlated with low frequency of pain behavior in RA and is related to physical and mental

health in SLE (238,239). Coping strategies involve motor and cognitive actions to control the impact of stresses. Passive coping strategies are associated with high pain levels, disability, and poor illness adaptation (230). Psychosocial interventions help improve pain, affect, and function (239–241). They may also increase self-efficacy and health status. RA patients who use stress management programs increase self-efficacy and improve ratings of depression, pain, and walking speed (242). Treatment offered through telephone-based interventions has been associated with psychological improvement in SLE. Audiotapes and videos used at home yield improvements in physical function, pain, joint count, and global scores in RA (230). In summary, psychological and behavioral approaches are very useful in RD (243,244).

### ***Sexual Adjustment***

Many normal, well-educated, financially successful, and maritally stable U.S. adults admit to sexual dysfunction or difficulties. However, arthritis may impose additional limitations or alterations that influence the sexual life as they do other ADL (245).

Particular sexual problems in the arthritic patient arise as a result of mechanical problems associated with decreased ROM, pain, and stiffness; depression, with decreased self-image and interest; drug therapy resulting in decreased libido; psychosocial problems in the family unit related to the patient's arthritis; and fatigue. Studies indicate that impairments occur in various indices of sexual function in a number of autoimmune diseases. In PSS, vaginal dryness, ulcers, and dyspareunia are significantly more common after disease onset in comparison with SLE and RA controls (246). Dyspareunia is also common in Sjögren's (247). There is a 50% decrease in the number and intensity of orgasms. Sexual satisfaction index is impaired in all three groups. Skin tightness, reflex, heartburn, and muscle weakness adversely affect sexual relations, more in PSS than in SLE and RA (246). Impotence occurs in males as a result of neurovascular problems in PSS and related syndromes (248).

**Joint stiffness and mechanical problems.** Arthritic involvement of the hips, knees, lumbar spine, hands, and shoulders commonly causes joint stiffness and painful mechanical problems that interfere with sexual performance. Hip involvement commonly causes mechanical problems. Analgesics and warm baths before intercourse may help. In women with more advanced disease, a posterior approach by the man for intercourse may be successful. With severe limitation of motion, either unilateral or bilateral hip replacements may be a requisite to achieve intercourse. After hip surgery, intercourse should not be resumed at all for 6 weeks, and hip flexion of more than 90 degrees should be avoided. Attention to sexual adjustments after joint replacement is important (249). Neither pain, nor stiffness, nor limitation of motion of the knees should mechanically limit intercourse, but a change in position may be required for more comfort. For those patients with back pain (e.g., spondyloarthropathies, disc disease), a lateral position for both the man and the woman is preferable. Patients with significant muscle weakness, as in DM-PM, may need to assume a more passive sexual role.

Significant problems in the joints of the hands and arms, as in RA, are more restrictive for the man than for the woman; a side-lying position may alleviate this. In both men and women, arthritis of these joints may interfere with the early stages of lovemaking involving caressing and manual stimulation.

**Self-image.** Often arthritic patients experience a decrease in self-image, a feeling of helplessness, and ultimately depression, which in turn is associated with decreased libido. Chronic pain may reduce a woman's efforts to make herself more attractive for her partner, and it is difficult to reassure the woman who has significant joint deformities that she is still physically attractive. A man may abstain from sexual relations rather than cause his arthritic spouse pain, and the spontaneity is reduced. In comparison to RA patients with a low degree of morning stiffness, RA patients with a high degree of morning stiffness worried more about self-image and reported significantly more problems in sexuality (250). Appropriate counseling may help alleviate these problems.

**Medications.** Certain medications are associated with decreased libido. High-dose steroids used in SLE and DM-PM may affect the physical appearance and contribute to decreased self-image or acceptance by one's spouse. Immunosuppressive medications may interfere with conception. Reports have been published regarding gynecomastia and sexual impotence associated with MTX (251). Many of the medications used to manage the RDs may cause significant fatigue. Education about energy conservation and the practice of aerobic exercise may be generally useful in managing this symptom.

**Psychosocial problems.** Psychosocial problems in the family unit may lead to decreased sexual relationships between husband and wife. Such problems include inability to work, inadequate finances, limited acceptance by friends, and limited participation in social or recreational events. Misunderstanding and anxieties of the children about the chronic disease of the parents also contribute to tension and adversely influence sexual relationships.

Patients with JIA had similar attitudes toward sexual activity, conception, wish for children, age at first child, and duration of lactation. However, fecundity is significantly decreased and an increased miscarriage rate has been reported. Males had greater problems than females in establishing relationships (252). Successful treatment of musculoskeletal disease does not necessarily serve as a sexual restorative; rather, understanding, counseling, alterations in sexual positions, or appropriate joint replacements are necessary.

### ***Vocational Aspects***

A vocational assessment should be part of the workup for RD patients and should cover educational level, work history and achievements, physical functional level, and social and psychological adjustment. The capacity of individuals with RD to work is decreased when compared with those without RD (253,254), and those with RA are particularly impacted. Three years after diagnosis with SLE, 40% patients are no longer working (255). For those patients who work as homemaker, the RD has a negative impact on family activities and function (248).

Determinants of work disability exist at societal and individual levels (256). Societal factors include economic conditions, attitudinal and architectural barriers, types of jobs available, employers' practices, and types of disability pension plans available (253,254). Individual determinates are disease, social factors, and ability to maintain locus of control and anatomy on the job (252,256). Functional status is the most important determinant of household work performance (257,258).

A recent study indicates that women have higher degree of work disability in RA (259). Remaining in the work force or being a homemaker is an important goal for the person with arthritis, and rehabilitative care and the support of the family help ensure success. The first step in vocational counseling is to see if adjustments can be made in the job or home setting so that the patient can continue working. If changes cannot be made, then the patient may have to receive formal vocational rehabilitation, or training for another vocation.

### Specific Diseases

#### Rheumatoid Arthritis

RA is a systemic RD characterized by an acute inflammatory response. It has different patterns of onset and can be divided into different types (Table 40-15) (260).

Depending on the severity of the progression of the disease, the pathologic process of RA has impact on joints, their surrounding structures, and other major organ systems. This process can produce a number of physical (anatomic and physiologic) and psychological (mental and emotional) impairments. These impairments cause functional problems that can result in disability. Table 40-16 lists the potential variables that can influence the extent of impairment, functional decline, and disability.

#### Course and Disease Outcome

Fewer than 25% of RA patients have a true remission in 5 years (260), as measured by ACR criteria. Most have progressive disease of varying degrees. The rate of progression to

joint destruction and disability is proportional to the intensity of the inflammation, proliferative reaction in the joints, and persistence of disease over time. Low-grade attacks of synovitis, separated in time, are less likely to cause joint deformity than continuous active synovitis. Radiographic progression is highest in the first few years of the disease but can progress over decades. Once the synovium begins to destroy and invade cartilage, it is at risk for irreversible damage even if disease activity decreases (260,261).

In the 1980s, studies indicated that RA patients had a progressive decline in functional capacity, ability to work, and increase in mortality rate of 5 to 20 years (260). Work disability after 5 years is 60% to 70% in RA patients under 65 years of age (262). Other studies have developed models using baseline indices to predict outcome in RA (263,264). This information has been useful to clinicians in planning treatment (Table 40-17). One study predicted increased disability by both disease factors and nondisease variables. Several comorbid conditions may contribute to disease mortality (Table 40-18). Disease-related factors explained 33% of total disability, and nondisease factors (depression, education, psychological status) explained 26%. Unexplained were 41% (264). Similarly, disease mortality has been predicted and 5-year survival has been reported as 85% to 95% in patients who had favorable baseline variables versus those who had unfavorable baseline variables and who had a mortality rate of 45% to 55% (265).

**TABLE 40.15** Onset and Types of RA

Onset
Insidious over weeks to months, 65%
Acute over a few days, 8%–15%
Intermediate over days to weeks with more systemic complaints, 15%–20%

### Treatment of RA

Early aggressive pharmacologic treatment by rheumatologists has been shown to be associated with improved function in early RA (4). Early functional assessment and a multidisciplinary team approach to patient management and rehabilitation have shown benefit in improving clinical outcomes (266).

To best treat patients with RA, the physiatrist should be aware of a number of entities (Table 40-19). All these are important because they influence the type, intensity, and frequency of prescribed treatments. They help in setting up appropriate precautions and in determining if other medical or

rehabilitation consultation needs to be made before treatment initiation.

RA is associated with a high degree of disability, the causes of which have been frequently attributed to impairments and the biology of the disease. Recent literature suggests that the radiologic appearance in those with RA correlates highly with measures of functional ability (HAQ and AIMS) (267,277). Critical to the management of RA should be treatment aimed at preventing disability and preserving or improving function. Usually these include muscle strengthening while protecting joint integrity (isometric exercise may be preferred), aerobic conditioning using low-impact methods, and encouragement of leisure activity that promotes socialization and well-being (268,269).

### Impairments in RA and Treatments

See Table 40-20 for a listing of rehabilitative treatments and functional deficits and disabilities in RA.

**Pain.** Among patients with RA, 70% seek help for pain (270). Pain in RA is caused by active synovitis, stretch of the joint capsule by effusion, mechanical joint destruction, and moving and loading joints. Pain is complex and has physiologic and subjective components. It contributes significantly to functional disability in early RA (271). Treatment includes education, exercise, stress management, medication, physical modalities, orthotics, assistive devices, and joint protection.

**Fatigue.** Fatigue is one of the most common impairments in RA. Characteristics of fatigue are varied and may include inability to sustain daily routines or leisure activities, sleepiness, inability to wake up refreshed, depression, and muscle weakness. Treatment is targeted at the most likely organ system contributing to the symptom. For example, sleepiness or lack of refreshing sleep may best be treated with medication for

**TABLE 40.20 Rehabilitative Treatment of Impairment, Functional Deficits, and Disabilities in RA**

	Deficit	Treatment
Impairment	Pain	Medication, education (self-efficacy), stress control joint protection, orthotics, assistive devices, in modalities, exercise
	Fatigue	Energy conservation, depression management, exercise (strengthening/aerobic) short rests
	Joint swelling (acute inflammation) (subacute/chronic)	Cold pack, ROM, heat, exercise (strengthening/aerobic)
	Weakness	Exercise (isometric/isotonic/isokinetic)
	Deconditioning	Aerobic exercise, energy conservation, short rests
	Joint effusion	Remove before exercise program (if clinically significant)
	Limited joint motion	ROM/strengthening (if biomechanically stable, not ankylosed and 0 to mild effusion), modalities
	Depression/anxiety/stress	Medication, counseling, relaxation techniques, coping, strategies
	Sleep disturbance	Medication, modalities before sleep, naps, stress reduction, mattress, and pillow changes
	Sexual dysfunction	Education, counseling, address course
Functional	Mobility	Gait aides, scooter
	ADL	Assistive devices, joint protection, education environmental strategies
	Gait	Assess cause of deviation, gait aids, appropriate shoes, and orthotics
	Homemaking	Environmental adjustments, adaptive devices, energy conservation joint protection
Disability	Can't work	
	Can't do housework	Vocational assessment; possible retraining, environmental adjustments
	Can't care for self	Home assistance, scooter/wheelchair, environmental changes

sleep. Muscle weakness, on the other hand, is best treated with a strengthening program, and endurance problems are likely to respond to aerobic conditioning. Interrupting activity with periodic rest (20-minute naps) during the day has been shown to be effective in increasing physical activity (PA) levels (272). Also to be included are energy conservation techniques and depression management.

**Decreased aerobic capacity.** Deconditioning contributes to decreased aerobic capacity. Patients tend to limit activities because of joint pain fatigue and decreased motivation. Cardiovascular problems due to RA or other diseases may contribute. A 2006 internet-based PA program for RA with individualized guidance (IT) versus general information (GT) showed the IT program was more effective with respect to the number of patients who report meeting PA recommendations than the GT program. This program is inexpensive and readily accessible and should be useful for RA patients who have limited activity levels (273).

Aerobic capacity in RA is commonly evaluated by submaximal aerobic testing. A recent 2008 study identified that a HAP is useful in estimating fitness levels when aerobic standard testing is not feasible (274). Aerobic training has proven to be of benefit for class I through class III RA. It is generally of low intensity in class III or of moderate intensity in classes I and II (Table 40-21). Appropriate forms include cycle ergometer, land (low-impact) dance or aerobic routines, or water aerobics. The latter is appropriate for class III deranged joints or

joint replacements. Aerobic exercise can improve function and increase aerobic capacity without increasing inflammation, if chosen appropriately.

**Sleep disorder.** Several different types of sleep disorders exist in RA: (a) fragmented with nocturnal clonus, (b) frequent prolonged wakefulness after sleep onset, and (c) sleep apnea. Insomnia or early AM awaking is not common. Treatment consists of modalities and appropriate pain medication before bed, and provision of a good mattress or pillow. Medications such as clonazepam, L-dopa, short-acting benzo-diazepines, and zolpidem can be used to improve sleep quality and quantity.

**Depression.** Depression can often accompany RA but is no more common in RA than in other chronic disorders (275). Depression and its subtypes in RA are correlated with health status measurements. Stress and anxiety are common. Appropriate treatment for depression includes treating the underlying cause and medication. Depression, stress, and anxiety may benefit from stress management, relaxation techniques, and coping strategies.

**Decreased strength.** Strength deficits occur very early in RA and are due to atrophy around painful joints, reflex inhibition by pain and joint effusion, inactivity, and myositis, which may be associated with RA. Muscles around key joints (particularly the knee, hip, shoulder) should be strengthened. The literature provides evidence that isometric, isotonic (low- and moderate-resistance exercise) (163,199), and isokinetic exercises all strengthen muscles in RA. In addition, exercise as

**TABLE 40.21** Exercise Type Recommendations for Specific Joint Conditions and Functional Level

AROM, active range of motion; R, resistance; I, intensity.

part of aerobic and aquatic programs also yields strength gains. Isotonic resistive exercise yields more gains than isometric exercise. The types of exercise, the intensity, and the frequency depend on ACR functional class, presence or absence of joint effusion, biomechanical joint integrity, inflammation stage, presence of moderate to severe OP, and presence of joint replacements (see Table 40-21). In general, keep the exercise simple, meet needed patient goals, and follow exercise guidelines for compliance (see Table 40-9). RA is a chronic disease that needs continued physical exercise with sufficient intensity to prevent decreases in muscle strength and function loss (276).

**Decreased ROM.** In early RA it is important to prevent contracture. In later stages contractures may be present. Patients should be on a basic ROM program daily for all affected joints. In patients with limited ROM, due to contracture, ROM exercise should be in the available arc of motion.

**Functional problems.** Such problems as decreased mobility, compromised ADL, and impaired gait are common in RA. Determining the impairments that produce these problems is necessary. The impairments should be managed appropriately.

This will help reduce the functional limitation. Education on use of gait aids and assistive devices, orthotics, and environmental strategies is needed (see Table 40-20).

**Disability.** Although past studies indicate a significant number of persons with RA experience work and household disability, newer pharmacologic agents and early rheumatologic and rehabilitative care have resulted in improved function and less disability (277).

Management includes investigating the impairment and functional problem contributors to disability. Recently, subclinical disability, a need to modify task performance or frequency without reported difficulty with the task, has been identified as part of the disability continuum. Seventy-five percent of a group of RA patients identified difficulties with valued life activities (VLAs). They were significantly more likely to experience functional limitations over a 2 year period. Subclinical disability may be a valuable marker of those in a disability transition phase where intervention may help maintenance of function (278). Intervention by vocational rehabilitation with patient interview and workplace assessment is

essential. Ergonomic assessment may help people with arthritis maintain employment. An ergonomic assessment tool was developed and was shown to be feasible and comprehensive in identifying job issues that need accommodation strategies (279). All factors influencing disability need to be addressed, since workplace accommodations alone may not be associated with improvement in employment rate (280).

**Specific joints.** RA may cause a variety of specific joint impairments that primarily affect the synovial lining of diarthrodial joints. It can affect almost any and all the peripheral joints, with relative sparing of the axial spine, except for the upper cervical (i.e., atlantoaxial) joints. However, degenerative change frequently accompanies it and involves C4-5 and C5-6 and the hands, knee, hips, and metatarsal phalangeal (MTP) joints. The end result of the process is joint pain, swelling, and malfunction. The muscles that surround the swollen, inflamed joints, or biomechanically compromised joints, are painful and are often atrophied or myositic. Ankylosis may occur, but subluxation is more common. Malalignment and pain result in increased problems with ADLs, mobility, and energy expenditure. Pain and deformity may cause problems with self-image and sexual activity (260).

**Joint-specific problems.** Shoulder RA affects the glenohumeral joint, distal third of the clavicle and surrounding bursae, capsule, and ligaments. Arthritis is associated with pain in the shoulder girdle, which is referred to the neck, back, and upper arm. Decreased motion of the joint, soft-tissue contracture, and muscle atrophy follow. Because the capsule lies deep under the rotator cuff, effusion is difficult to detect on physical examination. Static and dynamic rotator cuff exercises in mild RA decrease arm pain, help swollen joints, and improve SIP scores (281).

Pain causes decreased ROM. Limitation of IR is seen early. Proximal subluxation of the humeral head occurs late in the disease. Weakness of the rotator cuff may cause superior subluxation in about 33% of RA patients; about 21% of patients develop rotator cuff tears; and an additional 24% have fraying of the tendons (260). The insertion of the rotator cuff tendon into the greater tuberosity makes it vulnerable to erosion by synovitis. Adhesive capsulitis, with anterolateral shoulder swelling, subacromial and subdeltoid bursitis, and bicipital tendinitis are associated problems. Anterolateral soft-tissue shoulder swelling can indicate subacromial bursitis.

Adhesive capsulitis with motion loss can occur quickly. Pain is worse at night, when sleep movements stretch the capsule. Full motion is not needed for most daily activities, so pain may be less during the day. In addition to pain control with heat and cold, local steroid injection into the specific affected area is often useful. A ROM program to increase and prevent loss of mobility is crucial. For functional activities, the shoulder must have 30 to 45 degrees of flexion and 10 degrees of IR. Care must be taken to assess the degree of radiographic involvement and joint stability when prescribing mobilization so as not to injure a compromised joint. When pain and inflammation subside, Codman exercises and the use

of a cane or wand can increase flexion and IR and ER. Wall walking is good for chronic capsulitis. In the presence of adhesive capsulitis, a technique of abduction-ER-flexion traction for 1 hour a day, in conjunction with transcutaneous electrical nerve stimulation (TENS), has been successful in decreasing pain and increasing ROM (147). Isometric strengthening should first focus on the deltoid with the shoulder adducted, then wrist-restricted isometrics in IR and ER; finally, triceps and biceps isometrics are added. Instruction in joint protection is essential to avoid overusing the shoulder. Arthroplasty should be considered before end-stage erosion and soft-tissue contraction occur.

Elbow involvement is common in RA (20% to 65%), depending on disease severity, with loss of full extension being an early problem. Loss of lateral stability can cause significant impairment. Preservation of flexion is needed for ADL. In severe disease, lateral stability may be lost, which may cause significant pain and disability in ADL function. Olecranon bursitis and accumulation of RA nodules that may breakdown easily are annoying to the patient (260).

Bursitis may be caused by *Staphylococcus* infection, and care must be taken not to inject the bursae of the elbow with steroid before a culture is performed. Wearing a padded Heelbo (Heelbo, Niles, IL) is useful to relieve pressure.

Lateral and medial epicondylitis is common. Acute epicondylitis is managed with cold modalities. Steroid injection may be necessary. Stretching exercise should not be forceful because articular damage is often present in the arthritic elbow.

The hand and wrist function as a unit. With weakness of the extensor carpi ulnaris, the carpal bones rotate (i.e., the proximal row in an ulnar direction and the distal ones radially), resulting in ulnar deviation of the MCPs. A power grasp and weakened intrinsics accentuate these problems.

Synovial proliferation increases pressures in the wrist joint, so that ligaments, tendons, and cartilage may begin to be destroyed. When the ulnar collateral ligament is stretched or ruptures, the ulnar head springs up dorsally and floats. In advanced disease, the carpus becomes significantly compacted. Carpal tunnel syndrome may occur bilaterally. Progressive wrist disease results in decreased motion or ankylosis if the disease is severe and of long duration.

In the hand, muscle weakness and contraction occur and grip strength decreases. One study of male and female RA patients (disease duration mean of 7.5 years) followed for 5 years, showed at the 5-year mark that grip strengths, Keitel function test, and HAQ scores were significantly worse in women. One fourth of patients in both groups needed more ADL assistance (282).

Swan neck deformity flexion of the distal interphalangeal joint (DIP) and hyperextension of the proximal interphalangeal joint (PIP) occur, as does Boutonniere deformity when the extensor hood of the PIP is stretched, causing flexion of the PIP and hyperextension of the IP. With incomplete profundus contraction, limitation of full flexion occurs at the DIP joints. Similarly, tight intrinsics prevent full flexion of the PIP joints with the MCPs in extension.

Three types of deformity occur at the thumb:

*Type I:* A boutonniere-type deformity at the IP joint (i.e., Nalebuff)

*Type II:* Volar subluxation at the CMC joint during contraction of the pollicis adductor

*Type III:* In severe disease, exaggerated adduction of the first carpometacarpal joint and flexion at the MCP, and hyperextension at the DIP joint

Flexor tenosynovitis and de Quervain thumb extensor synovitis are common (260).

Rehabilitative hand care involves stretching of tight intrinsic and exercise. A controlled study of hand exercises versus no exercise for 48 months in female RA patients showed a significant increase in grip strength and pincer grip strength in the exercise group. The control group showed a significant decline in these parameters (283). A 3-week randomized control trial of combined ice massage and wax treatment and thermal and faradic baths with exercise revealed significantly improved Richie articular index, hand pain, ADL score and grip strength, and ROM in the treatment group. All parameters slightly declined in the control group (284). Use of functional wrist splints and finger ring-type splints to help reduce hyperextension or fixed flexion deformities, joint protection techniques, and postoperative care are important. These splints may help decrease synovitis, relieve pain and edema, and, when worn, reduce deformity and possibly retard its progression. A study of 273 RA patients indicated that in those with disease of less than 5 years, 269 needed help from a person in ADL activities. The highest amount of disability resulted from impairment of the wrists. This indicates that early attention should be paid to treatment and stabilization of the wrist (285).

**Lower-extremity joints.** The hip, knee, and foot-ankle are weight-bearing joints and cause greater pain and dysfunction than upper-extremity joints.

About 50% of patients with RA have radiographic hip involvement (260). Since this is a deep joint, early inflammation is not apparent. Palpation of effusion is difficult. Synovitis of the hip can cause pain radiating to the groin, whereas trochanteric bursitis causes pain radiating over the lateral thigh but can be in the buttock, anterior thigh, low back, and knee. Collapse of the femoral head and remodeling of the acetabulum, which is pushed medially (i.e., protrusio), occur in 5% of RA patients. Reduction in IR is an early finding with hip involvement. Synovial cysts can develop around the hip joint and communicate with the trochanteric bursae. Hip effusion can inhibit contraction of the gluteus medius muscle.

ROM exercises are important, first to maintain at least the crucial 30 degrees of hip flexion. A tight tensor fascia lata should be stretched. Stretching in abduction helps to relieve pain. Stretching of the internal and external rotators, extensors, and abductors should be followed by isometric strengthening exercise for the hip abductors and extensors. Ultrasound is best avoided in RA of the hip because it is somewhat difficult to assess the state of the inflammatory process in this deep

joint. Because ultrasound increases joint temperature, it may aggravate an existing acute or subacute process.

The knees are commonly involved in RA, and synovial inflammation and proliferation and effusion are easily seen. Quadriceps atrophy occurs within weeks of the onset of the disease and leads to increased forces through the patella to the femoral surface. Loss of full knee extension also occurs early, and fixed contractions may ensue. Patients with lower limb involvement have been found to have quadriceps sensorimotor dysfunction that was associated with lower-limb disability. A clinically applicable rehabilitation program increased quadriceps sensorimotor function and decreased lower-limb disability without exacerbating pain or disease activity in well-controlled RA (286).

One study describes kinematic gait analysis difference in two groups of RA patients: (a) knee joint involvement and severe inflammation without progressive destruction and (b) knee joint involvement with progressive destruction. This analysis, which showed limitation in knee angle changes in swing and stance phases as well as a shortened swing phase duration in inflamed knee joints, can provide practical information about functional joint integrity in RA that could aid in therapeutic decision making (287).

In the presence of moderate to large joint effusion, knee flexion in excess of 20 degrees is associated with significant increased articular pressure, and caution must be observed in performing ROM exercises on a knee with significant fluid, as outpouching of the posterior joint space may occur, creating a popliteal or Baker cyst. Fluid from this popliteal portion does not readily return to the anterior joint space, but rather adds increased pressure to the popliteal space. Forceful ROM may also cause rupture of the capsule. There may be uncomfortable fullness or pain in the popliteal space, and rupture into the calf may simulate thrombophlebitis. Ultrasound can define a cyst. If rupture occurs, a hematoma may be seen below the malleoli. Observe the patient from the rear while he or she is standing to check for a popliteal cyst.

Meniscal cartilage and cruciate ligaments can be easily destroyed by proliferative synovitis. Collateral ligaments become stretched, causing valgus and varus deformity. Tests for knee stability are always indicated in an examination. X-rays should be taken in the standing position to assess the cartilage and joint space.

Treatment is directed to the particular focal intra- or peri-articular problem. The patient should be instructed in early ROM exercise to preserve knee extension and flexion. Ninety degrees of knee flexion is needed to kneel, and 100 degrees is needed to climb stairs. A pillow under the knee at night is to be avoided because this will encourage a knee flexion contracture. Stretching of the hamstrings is important. Strengthening of the quadriceps mechanism in nonacute joints by isometrics and in nonacute or subacute joints by low- and moderate-intensity isotonic exercises in 30 degrees flexion, if performed early in the disease process, helps to maintain the biomechanical advantage of the knee. Higher-intensity isotonic exercise should follow for the noninflamed joint.

Moderate to large effusions that inhibit contraction of the quadriceps and contribute to knee pain are best removed. Weight-bearing restrictions regarding the knee are indicated with acute flares. Bracing the knee for instability is possible (see the section “Orthotics”), but patient compliance is low with bulky braces. Inflamed periarticular or articular structures respond favorably to ice massage. When the joint is subacute or chronic, moist hot packs and TENS can be used.

Arthritis affects the MTP, talonavicular, and ankle joints in descending order. Ankles are less frequently involved than knees. Ankle damage is usually present in severe or progressive RA. Synovial involvement can be prominent and is seen anterior and posterior to the malleoli. The tarsal tunnel, posterior and inferior to the medial malleolus, contains the posterior tibial nerve, which is often painfully compressed by synovitis. In acute disease, stretching and erosion of collateral ligaments around the ankle occur, resulting in incongruity and usually pronation of the hindfoot. Subtalar joint involvement is common, and patients experience more pain walking on uneven ground. About 85% of patients with RA have forefoot problems, such as widening at the metatarsal area, prominent MTP joints caused by subluxed metatarsal heads, hammer toe deformities, and hallux valgus of the great toe. Areas of skin breakdown are common on the dorsum of the toes (i.e., hammer toes), and callus is seen under the MTP heads. Plantar fasciitis and sub-Achilles bursitis may occur. Gait is typically flat-footed with little heel-strike or toe-off and a shuffling gait. Pronation of the hindfoot can be prominent. Appropriate footwear is extremely important. RA of the hindfoot and ankle can produce considerable dysfunction. A variety of nonoperative treatments may slow the progression of deformities, improve function, and provide symptomatic relief (288).

### PM and Inflammatory Myopathies

DM-PM, IBM, and their subsets are systemic RDs that affect skeletal muscle. The clinical picture is predominantly one of profound weakness of the shoulder and hip girdle muscle, as well as of the neck and pharynx. In severe cases the diaphragm, intercostals, and abdominal muscles are involved. Twenty percent of patients with DM-PM also have some distal muscle weakness, and 50% of IBM patients have distal weakness. Some have weakness of the respiratory muscles. The muscle weakness is often compounded by steroid myopathy. A fair amount of muscle pain may be experienced when the inflammation is active. There may be complete remission of the disease, but chronic weakness is more common. Episodic periods of remission and exacerbation, which are often unpredictable, pose problems with functional activities and maintaining work status.

The inflammatory myopathies (18) can be divided into six major types:

*Type I (PM):* insidious onset, beginning in the pelvic girdle and later progressing to the shoulder girdle and neck muscles. Weakened posterior pharyngeal and laryngeal muscles result in dysphagia and dysphonia. Remission and exacerbations are

quite common. Moderate to severe arthritis as well as Raynaud phenomenon may be present. The skin over the knuckles and elbows is often atrophic.

*Type II (DM):* acute onset. Proximal muscle weakness and an erythematous heliotropic rash on the skin of the eyelids and the dorsum of the hands are seen. Muscle tenderness is encountered in 25% of cases; subacute joint findings are common, as are systemic manifestations of malaise, fever, and weight loss.

*Type III (cancer-associated myositis):* associated with malignancy and most common in men more than 40 years of age. Often, muscle weakness precedes the diagnosis of malignancy by 1 to 2 years. The muscle weakness is usually progressive and does not respond well to steroids. Dysphagia and respiratory muscle weakness are common events. The mortality rate is high, and death is often the result of respiratory failure and pneumonia.

*Type IV (JDM):* involves children. The muscle weakness is rapidly progressive, and problems with dysphagia, dysphonia, and respiratory weakness are quite common. It is important to remember that late exacerbations occur after 7 years of remission. The propensity for the development of severe joint contractures and muscle atrophy is high. Skin problems in the form of calcinosis universalis (i.e., cutaneous and muscle calcification), particularly over bony prominences, contribute to skin breakdown, draining lesions, and joint contracture (289).

*Type V (myositis associated with other collagen vascular diseases):* namely, RA, SLE, and PSS. The functional problems associated with the individual collagen disease often dominate the clinical picture.

*Type VI (IBM):* most commonly involves men more than 40 years of age and has a slowly progressive course of muscle weakness. The quadriceps, hip, and shoulder girdle muscles often develop profound atrophy. In addition to proximal weakness, 50% of patients have significant distal weakness.

Each subtype has specific problems and impairments. Rehabilitation of the patients with DM-PM is influenced by the specific subtypes. However, there are some common impairments in the subgroups on which rehabilitation goals and treatment can be formulated (289–292).

Newer studies have found that clinical and autoantibody subsets can determine 5-year survival. Existing clinical subsets and 5-year survival rate include cancer-associated myositis (55%), DM (80%), IBM (95%), and connective-tissue-related myositis (85%). Autoantibody subsets include anti-SRP (30%), antisynthetase group (65%), and anti-M2 (95%). These subsets also predict response to treatment. Subtypes based on autoantibody status present with a different set of problems (293). Antisynthetase syndrome consists of interstitial lung diseases, fever, arthritis, Raynaud phenomenon, and mechanic's hands. The disease often has a rapid onset and aggressive course. The arthritis can affect the hands, knees, elbows, and shoulders, and be chronic and deforming. The lung disease can be severe and can substantially limit ADLs and mobility.

Anti-SRP syndrome is associated with initial severe muscle weakness, myalgias, and cardiac involvement that significantly

impacts function. Anti-M2 presents with the rash of DM and cuticular overgrowth, and responds well to treatment.

Rehabilitation intervention must be tailored to suit the needs of each patient, depending on the disease type and associated impairments, functional problems, and disability present. Patients with type V PM and associated collagen vascular disease (e.g., PSS, RA, SLE) have muscle weakness plus the added problems of the additional disease, which needs to be addressed from a rehabilitation standpoint.

### ***Survival and Prognosis***

Much has been learned about medical management and the efficacy of rehabilitation of patients with DM-PM in the past 10 years. In earlier years, DM-PM had a high mortality/morbidity rate, diagnosis was often made late, and steroids were the sole available treatment. Today better understanding of the types of PM, early diagnosis, expanded therapeutic regimens, and recognition of the importance of early rehabilitation intervention has helped decrease the mortality-morbidity rates.

General factors associated with poor survival are listed as follows: older age, malignancy, delayed initiation of corticosteroid therapy, myocardial involvement, pharyngeal dysphagia with aspiration pneumonia, steroid and immunosuppressive drug complications, and GI vasculitis (children).

Adults with type I and II disease can recover completely or be left with residual muscle weakness and fatigue, which can respond to rehabilitation management. The initial disease onset may be acute and require acute-care hospitalization for significant weakness with respiratory and swallowing difficulty. Rehabilitation must be provided from day 1 in a progressive manner. Transfer to a rehabilitation unit after acute-care management is appropriate (294). Patients with PM and associated incurable malignancy are not expected to recover from the disease. The rehabilitation goals are short term. Ambulation mobility and self-care functions progressively decline. Preserving ROM and strength will aid in keeping the person functional as long as possible. Not being able to continue in the work force for long is difficult for a middle-aged person to accept. Disability support payments and community support efforts need to be mobilized early on. Psychological support in coping with a chronic illness is needed. Good medical backup to contend with the problems of respiratory compromise and infection will be needed. Children with type IV disease need to be watched carefully for contractures.

Patients with type IV IBM have a slow, progressive course of proximal and distal weakness. Significant atrophy of the deltoid and quadriceps muscles is seen. Patients often have frequent falls resulting in fractures. The ability to increase the strength of significantly atrophied muscle has been shown to be poor (153). Lower-extremity bracing to support a weak quadriceps mechanism is often needed.

### ***Problems and Interventions***

Scientifically proven impairments in isometric (153), isokinetic strength (155), and endurance exist. Also studies document decreased aerobic capacity in DM-PM adults (159) and

children (160). The functional problems that arise depend on the muscle groups involved and the extent of the weakness. For example, weakness of the pelvic girdle muscles is associated with difficulty in rising from a chair or a prone position, difficulty going up stairs, difficulty getting in and out of a bathtub, frequent falls with difficulty returning to the standing position, waddling gait, and toe walking caused by heel cord tightness, which is common in children. Shoulder girdle weakness causes functional problems with dressing (e.g., difficulty pulling on shirt, hooking a bra) and grooming (e.g., combing hair, showering, shaving, brushing teeth), difficulty picking up heavy objects on a shelf, and difficulty eating. Neck weakness causes difficulty lifting and holding the head off a pillow and holding the head up while in a sitting position. Respiratory muscle weakness (e.g., intercostals, diaphragm) results in difficulty with respiration, causing shallow and sometimes inefficient respiration. Distal muscle weakness (seen in 10% to 50%) may cause foot drop and related ambulation problems and difficulties with hand function and activities (291).

Rehabilitation goals in the acute phase consist of maintaining ROM of the joints and preventing joint contractures (294,295). In the recovery phase, the goals are to increase and regain muscle strength, maintain ROM, return to functional ADL and ambulatory activities, and restore previous lifestyle activities as much as possible. UE ROM deficits are common in patients who have less than antigravity strength. The shoulder is most often involved in this case. Often knee flexion contracture occurs because of over pull of the stronger hamstrings in PM over the weaker quadriceps. Elbow, knee, and plantar flexion contractures are common in children, particularly those with skin/muscle calcinosis.

Patients with DM-PM/JDM should be on a basic ROM/stretching exercise program. These may have to be adjusted in patients with active calcinosis, as stretching could increase muscle inflammation and calcinosis. In JDM patients without acute calcinosis or rash, stretching exercise, casting, or dynamometers and aquatic exercise are appropriate. A recent text on the rehabilitation of persons with juvenile idiopathic inflammatory myopathy gives an excellent comprehensive overview of management of this patient group (292).

Isometric exercise is appropriate for DM-PM with inactive, mildly, and moderately active disease. Rest periods between contractions should be increased (20 seconds is appropriate) (153). Patients with significant atrophy are less likely to benefit. Therefore, early intervention is important. Clinically, low-weight concentric isotonic exercise is appropriate after a ROM and isometric program is in place in inactive and mildly active disease (173). (Both short- and long-term aerobic exercise are appropriate for inactive and mildly active myositis (174,175).) The efficacy of programs to increase the muscle strength by isometric (153), isotonic (185), and isokinetic exercise (191) without exacerbation of muscle inflammation, as determined by CPK, has been documented. The ability to increase aerobic capacity by short-term (6-week) and long-term (6-month) aerobic programs (176,186) has been documented.

Patients with significant quadriceps weakness often trip and fall. A study of an IBM patient yielded some reasons for this (296). Clinically bracing a patient with significant isolated quadriceps weakness on one side can help stabilize the gait pattern, make it safer, and reduce falls. The appropriate bracing in this instance is a short leg brace—either polypropylene or Klenzac—positioned in 5-degree plantar flexion to create a hyperextension moment at the knee that will stabilize the limb. In patients with bilateral quadriceps weakness, it is appropriate to brace the weakest knee. Both knees cannot be braced in this manner, as the center of gravity would be shifted posteriorly and compromise the patient's balance. In the DM-PM patient who has both significant proximal and distal weakness, use of a 90-degree brace at the ankle or with a 10-degree dorsiflexion assist increases knee buckling. A 5-degree plantar flexion brace would stabilize the knee and basically correct the ankle foot drop. For those patients (less common) with only significant foot drop a 90-degree or a 10-degree dorsiflexion brace is appropriate.

If pharyngeal and laryngeal weakness is present, referral to a speech pathologist to teach the patient techniques to avoid aspiration of food and prevent respiratory infection is needed (292). Neck flexor muscle weakness has been shown to correlate directly with swallowing dysfunction in patients with DM-PM, and its presence may cue the clinician to obtain a speech and language consultation (297). If respiratory muscle weakness is present, chest physical therapy breathing techniques, proper positioning, suctioning, postural drainage, and breathing exercises, if the patient is not in the acute stage, are indicated. Tidal volume should be checked daily with a bedside spirometer. A collar may be provided to support the neck when neck flexor or extensor weakness is present.

For muscle pain, gentle muscle massage may produce a sedative relaxing effect on the muscle. The use of heat therapy for this is poorly described in the literature.

Most patients with PM do not have arthritis. PM associated with anti-JO-1 antibody is characterized by arthritis that may become chronic and deforming without bony erosions. It occurs in the wrists, hands, elbows, knees, and shoulders. DM-PM with associated RD (e.g., RA, SLE, PSS) is frequently associated with arthritis, which can be deforming; therefore, the use of modalities, splints, and joint conservation techniques is needed.

Iatrogenic steroid problems cause vertebral compression fractures in the thoracic and lumbar spine, resulting in back pain and muscle spasm. OP is also common in the long bones and joints. Interventions include a corset to decrease spinal mobility, heat modalities to relieve pain, and a long-handled reacher and shoehorn. If avascular necrosis of the femoral head causes pain in the hip and groin on weight bearing, unweighting the hip is indicated. Deep heat (i.e., ultrasound) to the hip may relieve pain. Isotonic and isokinetic strength exercise should be available with moderate or severe OP.

Steroid myopathy presents with atrophy of muscle and increased muscle weakness. Repeated enzyme tests, electromyography (EMG), and muscle biopsy should be performed. If the enzymes have remained normal, biopsy shows no active

inflammation, and EMG is normal (only abnormal in rare cases of very severe steroid myopathy), the steroid should be reduced and the exercise program continued.

A number of problems can occur with the respiratory system. In addition to respiratory insufficiency, aspiration pneumonia may result because of weak pharyngeal and laryngeal muscles. Patients with the myositis-specific antibodies (MAS) anti-JO-1 commonly have interstitial lung disease. Primary interstitial fibrosis in JO-1 patients with PM associated with SLE, RA, and PSS may have lung disease associated with these diseases. Pulmonary rehabilitation may be indicated.

Cardiovascular complications with DM-PM include congestive heart failure (3.3%), cardiomyopathy (1.3%), cor pulmonale (0.7%), and electrocardiogram abnormalities (50%) (17). They are most common in type I and type V disease. Rehabilitation includes cardiac precautions, energy conservation techniques, and an endurance program.

Dermatologic problems include pressure sores over bony prominences (e.g., sacrum, elbows, heels). Extensive calcinosis seen in childhood DM-PM causes breakdown of the skin over bony prominences of joints with drainage of calcium oxalate. Vasculitis with ulcerations of the fingertips and toes may occur in the overlap syndromes. Preventive measures include proper positioning, good nutrition with adequate protein intake, use of an egg crate mattress pad or waterbed, and padded support over elbows, knees, and heels. Restoration measures include appropriate treatment if deep pressure sores are present.

Raynaud's syndrome precipitated by cold and stress is usually mild when it occurs, unless associated with collagen vascular disease. Symptoms include painful cold fingers and color changes from white to blue. Wearing gloves and using biofeedback have been useful.

### Systemic Lupus Erythematosus

SLE is a chronic, autoimmune inflammatory disease that can affect any organ in the body. The most frequently involved sites are the skin, joints, pleuropericardium, kidneys, and central nervous system. Its course is varied in severity and duration.

The rehabilitation team is often consulted with respect to a number of functional problems, and fatigue is one of the most common. The causes of fatigue are multifactorial and may result from deconditioning resulting from decreased activity, and release of inflammatory cytokines known to cause muscle atrophy and joint inflammation. These inflammatory cytokines may also influence mood and behavior. Interferon, TNF, and IL2 are associated with fatigue and lack of motivation. Medication used in treating SLE, such as prednisone, is known to cause type 2 muscle fiber atrophy, which may be associated with muscle weakness. Several studies have shown that fatigue is more prevalent in those with SLE than in those without, and that characteristically, it is least on awakening and steadily increases as the day progresses (298,299). This pattern is clearly different from morning stiffness, characteristic of RA and may be a result of

deconditioning rather than an inflammatory process. Physical findings in this patient group include muscle weakness, disruption of sleep/wake cycle, cognitive difficulty, and psychomotor slowing (300). Depression is reported in about 30% of patients with SLE (301).

Fatigue is the best predictor of disease activity (300). Patients with SLE have reduced peak  $\text{VO}_2$  and exercise duration. They also have reduced muscle strength and reduced forced expiratory volume (FEV) (302). A pilot study of 15 SLE patients aged 12 to 19 showed moderate impairment in aerobic fitness compared to referenced controls. Sixty-seven percent reported significant fatigue by questionnaire. There was no significant correlation between fitness and fatigue. Neither fitness nor fatigue is correlated with disease activity or damage, or quality of life (303).

The symptoms prevalent in the SLE population (fatigue, deconditioning, and disability) respond to rehabilitation interventions. Central nervous system manifestations, such as poor concentration and memory impairment, do not. Isometric and aerobic conditioning programs are feasible in this population and effective in increasing fitness, strength, and functional capacity. Patients with SLE have been shown to have decreased aerobic capacity (300,302). An aerobic exercise program has been shown to increase endurance by 20% (156). A RCT of adult SLE patients showed significant improvement in exercise tolerance and aerobic capacity, quality of life, and depression after a supervised cardiovascular training program when compared to non-exercising controls (304). Treatment may include an energy conservation training program teaching that PA should be combined with frequent periods of rest. Naps are taken during the day, and sleep can be promoted by the use of relaxation tapes.

Pain is common in the small joints of the hands and feet because of arthralgias and arthritis. Joint pain can also result from avascular necrosis of bone. Joint deformity is also seen. Control of joint pain has been successful with acupuncture and acupressure techniques, heat, cold, and TENS (305). These techniques are more effective in treating arthralgias than in treating avascular necrosis, which requires unweighting of the lower extremity. When unsuccessful, joint replacement to control symptoms may be required, but should be undertaken with great caution because of the high degree of joint laxity (Jaccoud arthropathy) which is often difficult to correct surgically.

The rashes associated with lupus are usually not responsive to nonpharmacologic treatments, but the skin ulceration that can occur as a result of active Raynaud's syndrome responds to hand-warming techniques (306). Temperature biofeedback has been used to relieve vasospastic disease.

Patients with renal disease often have diminished stamina and fatigue. Improvement will occur with good blood pressure control and management of edema. In patients with nephrotic syndrome and significant edema, care must be taken to position the limb in the most functional way to minimize contracture. Compression pumps and garments can be used to help with and maintain the reduction of limb edema. Precautions must be taken for patients with cardiac failure. They must be

compressed slowly or not at all because they may not tolerate any additional fluid load resulting from compression.

One of the major challenges to the rehabilitation team is the request to evaluate and treat patients with central nervous system involvement. Stroke, psychosis, depression, and memory deficits all have a significant impact on function. Treatment is aimed at the underlying problem. An uncommon but well-described problem is transverse myelitis. Management may require mobility aids, including a wheelchair. Reeducation in self-care skills and exercise to help promote stamina is needed. Spasticity may be controlled with oral antispasticity agents, or local neurolytic nerve blocks/chemodenervation. Treatment of flaccidity with braces or adaptive equipment should be offered. Speech therapy can provide strategies to enhance memory with the use of lists and cues.

In a study, in 109 SLE patients, of the impact of hand function on daily activities, 73% of them reported interference with ADL. Reduced grip strength, fumbling, and pain most commonly interfered with productivity (307).

The patient with SLE has to overcome major obstacles to successfully cope with this multifaceted illness. Support groups and family have been shown to be helpful in increasing compliance and are an essential component in the rehabilitation process.

### Systemic Sclerosis

Management of PSS presents a significant challenge for rehabilitation specialists. The primary organ affected is the skin, but the pathogenesis is microvascular damage that can affect the kidney, the lung, and occasionally the heart (308). Whereas internal organ involvement usually requires pharmacologic treatment (blood pressure control, possible treatment of pulmonary fibrosis), musculoskeletal involvement leads to soft-tissue contractures and loss of ROM for which rehabilitation interventions are often effective.

The skin in those with SS is often shiny and bound down, and is associated with loss of soft tissue. This is most obvious with the hands, where fibrosis of the skin (with or without calcinosis) causes contractures, depigmentation, telangiectasias, ulceration, and loss of prehension. Raynaud phenomenon often accompanies these findings.

The rehabilitation approaches include use of heat modalities. Care needs to be taken to avoid overheating relatively underperfused soft tissue that results from the microvascular damage. Paraffin and moist heat are usually best tolerated. Treatment of Raynaud phenomenon includes topical creams, such as nitroglycerine paste, and temperature biofeedback, as well as electric mittens. In general, heat and stretch programs are recommended, but little data is available to establish efficacy.

Several studies have reported beneficial effects of TENS and acupuncture. Both techniques are thought to increase skin blood flow through increased vascularization (TENS) or activation of vasoactive peptides (acupuncture) (309).

Joint contracture is a frequent result of skin thickening and contraction at the joint. Disuse leads to muscle atrophy.

Muscle may also be involved from an inflammatory process that begins as a cellular muscle infiltrate causing myositis and may lead to fibrotic change in muscle. This may be painful and may result in weakness accompanied by a rise in CPK and other muscle enzymes.

Physical medicine and rehabilitative treatment relies on a heat and stretch program of active or active assistive ROM. Active contraction of muscle is usually needed to restore or preserve functional ROM. Usually isometric exercise has been employed, but isotonic and isokinetic exercise appear to be well tolerated in many with RD. Slow-rate isokinetic exercise (<60 degrees/seconds) may be very stressful on inflamed joints. Adjunctively, splinting of the hand or wrist can be added to the heat and stretch program. Dynamic splinting appears to be ineffective and poorly tolerated (310).

The peripheral nervous system is commonly involved in SS, with a motor-sensory neuropathy (311), and occasionally autonomic dysfunction (312). Carpal tunnel syndrome is most commonly seen, although weakness of the long flexors may be seen as well (312). Proper joint positioning, avoidance of compression at bony prominences, and short-term functional splinting may be useful.

The impact of SS on function is often profound and may reduce work capacity. Job modification, protection from cold, toxic exposures (urea formaldehyde, benzene, silica, etc.) and work-site modification may help preserve function and reduce risk of exacerbation. Adjustment to illness often depends on psychosocial support and preservation of function (313,314). Provision of treatment improves the disease outcome (314). A review of clinical management is available for the reader (315).

### Spondyloarthropathies

AS and other related diseases (e.g., PSA, reactive arthritis, and IBD-related arthritis) constitute a group of disorders involving the axial skeleton, enthesopathy, and extra-articular manifestations (e.g., skin rashes/psoriasis, uveitis, and aortitis). They are known as spondyloarthropathies.

The disability resulting from these diseases is usually attributable to the loss of spinal mobility and reduced pulmonary function. The impairments include pain at the entheses, which is often worst at night and makes sitting difficult, and intervertebral fusion, producing substantial postural change.

Treatment for spondyloarthritis had typically consisted of NSAIDs, corticosteroids, and x-ray therapy, the latter two contributed to the development of OP. More recently, MTX, SSA and now TNF blockers such as etanercept have been used successfully.

Rehabilitation therapies have been aimed at reducing pain, preserving joint alignment and posture, and promoting independence in functional activities. Fitness training is essential to maintain independent function.

At disease onset the patient should be educated about maintaining mobility and preserving alignment. A ROM program designed to reduce hip flexor contractures and kyphosis should be initiated. Prone lying and sleeping without a pillow

are encouraged. Some degree of muscle strengthening and especially abdominal breathing should be instituted (316–319). Often therapies are suggested in conjunction with therapeutic pool/spa treatment, which seem to provide some symptomatic relief (320). One report describes the use of a Jewett spinal orthotic as an effective treatment for increasing spinal mobility and reinstating the lumbar curve (321).

Convincing data has been published for treatment efficacy of an intensive 3-week inpatient hospitalization (319). Using the Bath AS global assessment, disease activity index, and visual analog scale for stiffness, improvements were demonstrated that were significantly better than those not treated for a similar 3-week period.

Patients with AS must be counseled about potential risk of cervical spine fractures that may result in tetraplegia. Cervical fracture is much more common than thoracic or lumbar. The likelihood of spinal cord injury is 11.4 times higher in this group than in those without AS (322). The cause of injury was usually falling (53% of cases). Patients must be educated about self-protection to try to minimize injury, especially in the house, and to avoid contact sports, drinking and driving, and to keep homes well lit in order to prevent injury.

Hip arthroplasty has been performed for patients with AS, as has wedge thoracic osteotomy to correct thoracic kyphosis (323). More recent RCTs have looked at the benefits of various combined exercise programs (combined flexibility, strengthening, breathing, and posture) and the latter further combined with aerobic exercise in supervised outpatient versus home settings. Control groups have been: the same exercise, conventional or no exercise. Results in the nonaerobic studies have indicated significant benefits in the areas of flexibility and function in both settings. In the aerobic incorporated study, only the supervised outpatient group had significant improvement when compared to the home group during similar exercises (324–329).

A recent 2008 Cochrane Database Review of eleven AS trials, summarizes the scientific evidence on the effectiveness of physiotherapy interventions (individualized home exercise vs. supervised no intervention; supervised group therapy vs. individualized home exercise; initial inpatient spa exercise followed by outpatient group therapy vs. outpatient group therapy, and experimental exercise vs. conventional exercise). The author concludes that individualized home-based or supervised programs are better than no intervention, supervised group physiotherapy is better than home exercise, and combined inpatient spa exercise followed by outpatient group exercise is better than group exercise alone (330).

Evaluation of occupational status and conditions is important in AS patients. A study of 397 AS patients showed that those with jobs that required dynamic flexibility had more functional limitations than those without this requirement (bath ankylosing spondylitis functional index [BASFI] 48.3 vs. 38.1). A significantly increased BASFI and radiographic damage score was seen with dynamic flexibility and exposure to whole body vibration jobs (331). Reviews of treatment for AS are available (323,332).

### Juvenile Idiopathic Arthritis

JIA is an umbrella term now used to refer to a heterogeneous group of disorders of childhood onset that have in common chronic arthritis. The term JIA now replaces the older classification for JRA and juvenile chronic arthritis. JIA is defined by an onset before age 16 with arthritis affecting one joint or more joints for more than 6 weeks with no other known etiology (333). There are eight subtypes of JIA: systemic onset, oligoarticular persistent, oligoarticular extended, RF negative polyarthritis, RF positive polyarthritis, PSA, enthesitis-related, and undifferentiated. In general, the classification criteria for JIA are based on clinically presenting symptoms but also include exclusion criteria in defining each disease process. These exclusions include the following: (a) psoriasis or history of psoriasis in the patient or a first degree family member, (b) arthritis in an HLA-B27 positive male beginning after the sixth birthday, (c) AS, enthesitis-related arthritis, sacroilitis with IBD, RS, or an acute anterior uveitis, or a history of one of these disorders in a first degree relative, (d) the presence of IgM RF on at least two occasions in at least 3 months, (e) the presence of systemic JIA in the patient (Table 40-22). Each of these subtypes has an adult counterpart which may differ somewhat in presentation. JIA is more often manifested in large joints such as the ankles, knees, or wrists, unlike adult forms. Rheumatoid or subcutaneous nodules and RF are less likely seen in this population as well.

Early identification of the disease, advances in drug therapy, appropriate and well-timed surgical intervention, and early active ongoing team rehabilitation programs have contributed to better quality of life and functional outcome (334–336). Many patients who in the past were wheelchair mobile are now functionally ambulatory, with early diagnosis and intervention (337). A recent 2008 study of 106 JIA patients showed 66% have low PA levels (not meeting public health standards for moderate to vigorous exercise) and are at risk for further loss in PA benefits. Low PA was not related to disease activity. These patients should be urged to increase PA (338). A 2008 review of exercise in pediatric RDs reveals that exercise capacity is significantly decreased in a large number of JIA patients and is most common with active inflammation especially in girls with RF positive polyarticular JIA. Low levels of weight-bearing activity contribute to reduced bone mass, strength, and function. Increased levels of moderate to vigorous PA may improve exercise capacity, function, and general quality of life (338). Adults who have had JIA have significantly lower rates of employment and exercise tolerance than age-matched unaffected controls (339).

### JIA Categories

Systemic onset JIA is defined as arthritis in one or more joints with or preceded by fever of at least 2-week duration with at least 3 days of daily documented temperatures greater than 39°C, evanescent rash, generalized lymphadenopathy, hepatosplenomegaly or splenomegaly, or both, and serositis. In 50% of cases, five or more joints may be involved during some phase

of the disease. This group comprises 2% to 17% of children with JIA and has a M:F ratio 1:1 with peak onset 1 to 6 years of age. They often have growth delays, osteopenia, anemia, leukocytosis, thrombocytosis, and elevated acute phase reactants while RF positivity is rare. In milder cases patient will respond well to NSAIDs but in more involved case will require initial intravenous steroids followed by tapering oral regimens of DMARD therapy, with cyclosporine and MTX commonly being given. The newer biologic agents, such as anakinra, that are being studied, may show more usefulness in systemic onset JIA (340). The long-term prognosis is better for those with less severe arthritis. Patients who have systemic features; more than 6 months of polyarthritis with hip involvement, and thrombocytosis, have a poorer prognosis overall, and more of these children have long-term disability (341).

*Oligoarticular JIA* presents in two ways: (a) persistent oligoarthritis affecting one to four joints during the first 6 months of the disease; (b) extended oligoarticular arthritis affecting greater than four joint in the first 6 months. Females are affected at a 4:1 ratio to males, with peak age onset around 6 years of age. It is the most common of the JIA subtypes, affecting 50% to 60% of all children with JIA. The knee is the most commonly involved joint, followed by the ankle. Oligoarticular JIA may also involve the small joints of the hand and temporomandibular joint (TMJ). Chronic anterior uveitis is seen in 20% to 30% of those with oligoarticular JIA (342). ANA positivity is seen in 50% to 70% of these children and has a high degree of association with chronic anterior uveitis. Treatment algorithms for these patients may begin with NSAIDs but due to a low level of responders in this group, intra-articular steroid injections are more commonly used. Those with little or no response in these cases are treated with disease-modifying regimens such as MTX or anti-tumor necrosis antibody agents. In most cases, these patients respond well to pharmacological therapies, as 68% of those with the persistent type, and up to 70% of those in the extended oligoarticular group show improvement when treated with MTX (343).

*Polyarticular JIA* is divided into two subgroups which include: (a) JIA RF positive and (b) JIA RF negative. Both of these processes present with five or more joints involved during the first 6 months of the disease. The first of these groups differ with the presence of a positive immunoglobulin-M RF on at least two occasions, at least 3 months apart. Female predominance is seen with ratios of 9:1 and comprises 10% of total JIA cases. It is usually more aggressive, symmetrically affecting small joints of the hands, wrists and some larger joints similar to the adult form of the disease. Ten percent of those affected may have rheumatoid nodules. RF negative polyarticular JIA has the greatest risk for chronic, severe arthritis. It accounts for 30% of all cases of polyarticular JIA with a 3:1 female predominance. The joint distribution can be symmetric or asymmetric, affecting large and small joints that may include the TMJ and cervical spine. Positive ANA may be seen in up to 40% of cases and a higher risk for anterior uveitis is present.

TABLE 40.22 Juvenile Idiopathic Arthritis Subtypes

Type Classification	JIA Diagnostic Criteria	Peak Age of Onset	Sex Ratio (F:M)	% JIA	Systemic Manifestations	Articular Involvement
Systemic	Arthritis with or preceded by daily fever of at least 2 wk duration, documented to be quotidian for at least 3 d, and accompanied by at least one of the following: rheumatoid rash, generalized lymphadenopathy, hepatomegaly, adenopathy, hepatomegaly. <b>Exclusions:</b> a, b, c, d	2–4 y/o	1:1	10%	Fever, rash pericarditis, pleuritis, myalgias, hepatosplenomegaly, anemia	Knees, wrist, ankles > fingers, C-spine hips
Oligoarthritis, subcategory persistent	Arthritis in ≤ four joints at any time during the onset or course of the disease. <b>Exclusions:</b> a, b, c, d, e	<5 y/o	4:1	24%–58%	Anterior uveitis	Knees, ankles > small joints of hand, TMJ, C-spine
Oligoarthritis, subcategory extended	Arthritis ≤ four joints in the first 6 mo of disease but affecting cumulative total of ≥ five joints after the first 6 mo. <b>Exclusions:</b> a, b, c, d, e	<5 y/o	4:1	12%–29%	Anterior uveitis	(Same as persistent type) + wrist involvement
Polyarthritis RF negative	Arthritis affecting ≥ five joints during the first 6 mo with negative tests for RF. <b>Exclusions:</b> a, b, c, d, e	<6 y/o (+ ANA) 7–9 y/o (–ANA)	3:1	10%–28%	Uveitis	Small and large joints, symmetric or asymmetric C-spine, TMJ
Polyarthritis RF positive	Arthritis affecting ≥ five joints during the first 6 mo and positive test for RF at least twice 3 mo apart. <b>Exclusions:</b> a, b, c, e	>8 y/o	9:1	2%–10%	Rheumatoid nodules	Small joints (PIP, MCP, wrist, symmetric)
Enthesitis-related arthritis	Arthritis and enthesitis or arthritis or enthesitis plus any two of the following: • Sacroiliac joint tenderness and/or inflammatory lumbosacral pain • Positive HLA-B27 • Physician-diagnosed HLA-B27–associated disease in first- or second-degree relative • Symptomatic anterior uveitis • Male >6 y old at onset of arthritis or enthesitis. <b>Exclusions:</b> b, c, d, e	>6 y/o	1:7	10%	Anterior uveitis, IBD	Lower limbs and some spine involvement
Psoriatic arthritis	Arthritis and psoriasis or arthritis and at least two of the following: • Physician diagnosed psoriasis in first-degree relatives • Dactylitis • Nail abnormalities (pitting or onycholysis). <b>Exclusions:</b> b, c, d, e	7–10 y/o	2:1	2%–15%	Uveitis, psoriasis	Asymmetric small and medium-sized joints (knees, hands and feet) also large joints—knees and ankles
Undifferentiated	Arthritis, but does not fulfill any of the above categories or fits in more than one category. <b>Exclusions:</b> Not applicable	Variable	1:1	2%–23%		Variable

Exclusions:

(a) Psoriasis or a history of psoriasis in the patient or a first-degree relative.

(b) Arthritis in an HLA-B27+ male beginning after the sixth birthday.

(c) AS, enthesitis-related arthritis, sacroiliitis with IBD, RS, or acute anterior uveitis, or a history of one of these disorders in a first-degree relative.

(d) Presence of IgM RF on at least two occasions at least 3 mo apart.

(e) Presence of systemic JIA in the patient.

TMJ, temporomandibular joint; PIP, proximal interphalangeal; MCP, metacarpophalangeal; JIA, juvenile idiopathic arthritis; ANA, antinuclear antibody; IBD, inflammatory bowel disease; RF, rheumatoid factor.

In both types of polyarticular JIA early treatment with MTX is recommended. In RF positive patients with signs of progressive disease, MTX in combination with anti-TNF antibody agents is recommended, as this may play a role in preventing bony erosions (344).

*Psoriatic JIA*, which is a combination of arthritis and psoriasis, and accounts for about 10% of the total JIA cases with a 2:1 female predominance. Diagnostic criteria include: (a) dactylitis, (b) nail pitting and onycholysis, and (c) psoriasis in a first degree relative. The arthritis typically involves peripheral, asymmetric joints of the hands, feet, knees, and ankles. When joint involvement is limited, NSAIDs and intra-articular injections can be used initially. MTX is effective in treating skin involvement and anti-TNF antibody therapy is useful when the disease is most aggressive.

*Entesopathic JIA* represents about 10% of all JIA, and is characterized by arthritis, enthesitis, or both, in addition to any two of the following: (a) sacroiliac joint tenderness and/or inflammatory lumbosacral pain, (b) positive HLA-B27 antigen, (c) acute symptomatic anterior uveitis, (d) onset of arthritis or enthesitis in a male greater than 6 years old, or (e) physician-diagnosed HLA-B27-associated disease in first- or second-degree relative. The lower limbs and axial skeleton are most often affected. Other clinical manifestations include anterior uveitis, IBD, and a reactive arthritis. Treatment with NSAIDs for symptomatic relief of enthesitis is often given initially. Those with specific articular involvement may be treated with intra-articular corticosteroids, but may require DMARD therapy. MTX, SSA and more recently anti-TNF  $\alpha$  agents have been used as well.

Unclassified JIA are those subjects who do not fulfill any of the ILAR classification categories. This group comprises 2% to 23% of all cases at initial presentation of JIA. Of those classified as undifferentiated JIA, 60% showed no characteristic eligibility criteria for any of the other JIA categories while 40% had criteria from more than one specific category (345).

Special problem areas and impairments exist that deserve the attention of the rehabilitation specialist. Growth retardation, in general, may limit full stature. Abnormalities in growth related to specific joints result in a number of physical problems, cause impairment, and impact on function: short toes and fingers, leg length discrepancies, and micrognathia (i.e., small mandible). These abnormalities are due to premature closure of epiphyseal plates caused by intra-articular inflammation disturbing the development of the growth plate. Iritis and blindness are other major physical problems. It is important to remember that impairments of joint contractures and loss of ROM and muscle strength occur rapidly in JIA and must be managed quickly and efficiently. Impaired aerobic capacity is also present early in the course of the disease (346–349). Treatment goals should be determined as soon as possible, and treatments implemented early in the disease course.

### **Specific Problems**

**Upper limbs.** The wrist is often involved in JIA, and wrist flexion contracture can occur rapidly. A cock-up resting splint

should be used at night. If the wrist is inflamed or forearm muscles are weak, contributing to wrist flexion, a functional splint should be used for activities. If a wrist flexion contracture is present, serial casting may be needed. If there is PIP involvement, the resting splint should include the hand as well as the wrist. With IP joint contractures, a dynamic outrigger splint should be used during the day. If the elbow is acute inflamed, an adjustable hinge splint can be used. ROM exercises to maintain extension, pronation, and supination are important. If a contracture exists, serial casting can be performed.

**Spine.** Every effort should be made to avoid flexion contracture at the neck. Proper positioning at night with the use of a single thin pillow, like a pediatric Wal-Pil-O (Rolo, Culver City, CA), is recommended. Special attention to the cervical spine disease in systemic type and polyarticular RF negative JIA should be noted. When there is acute pain, a soft cervical collar is worn. Sometimes torticollis becomes a problem, and a firmer Plastazote collar may help. A collar is recommended for desk work. A desk with a tilt top may reduce pain and help maintain more ideal spinal posture.

**Lower limbs.** Knee involvement should be managed promptly. If the joint is acute, a posterior resting splint should be used at night to prevent flexion contracture. If contracture already exists, a posterior splint may increase the danger of tibial subluxation and should not be used. Rather, the contracture should be reduced with a skin traction device or by serial casting. Occasionally, soft-tissue release is necessary.

Valgus deformity frequently occurs, and a supracondylar osteotomy may be needed to achieve realignment if conservative measures fail. A hip flexion deformity contributes to knee flexion problems, and care must be taken to maintain hip extension. In severe disease, knee joint replacement can be considered if pain management and function cannot be achieved by medical and rehabilitative means.

An acutely inflamed hip joint is most often associated with acute muscle spasm and rapid formation of a flexion contracture. Often skin traction is used during acute hip pain to prevent contracture, with the patient lying supine in bed; 1 kg of weight for each 10 kg of body weight is used. In the child with a tendency toward knee flexion contracture, use of light hip traction during the night reduces the chance of the formation of hip and knee contractures. There should be periods of lying prone during the day to encourage maintenance of hip extension. A prone lying board also may be used in bed. If hip contracture is not responsive to conservative treatment, a soft-tissue release may be needed. Joint replacement may be needed in severe disease and is usually performed before 16 years of age.

**Ankle/foot.** Particular attention should be directed to management of the foot. Use of the proper shoe type and orthoses, as well as ROM exercise, is important. Leg length discrepancy should be corrected with a shoe insert or built-up shoe if a greater than 3/8-in. correction is needed.

Since patients with JIA have been demonstrated to have decreased ROM, muscle strength, and aerobic capacity, exercise

in the form of ROM stretching and isometric, isotonic, and aerobic exercise are recommended early in the treatment program. Since most children lose strength rapidly around inflamed joints (particularly the knee), a few isometric contractions daily are recommended even with an inflamed joint. Both the parents and the child should understand treatment regimens to ensure compliance. Many treatments are performed at home with parent's supervision.

Aquatic exercise has been shown to significantly improve hip motion (350). An 8-week weight-bearing conditioning program has been shown to increase the aerobic capacity in polyarticular JIA without disease exacerbation or increased pain (351). A RCT of 80 JIA children consisted of a low to moderate (as tolerated) aerobic experimental group, and a Qigong control group, both exercising three times a week for 12 weeks. Both groups showed significant improvement in childhood health assessment questionnaire (CHAQ) but not in aerobic capacity. Adherence was higher in the Qigong group (352). Children with JIA often have OP resulting from glucocorticoids, and weight-bearing activity has a positive influence on BMD (353).

The efficacy of exercise in RA has been reviewed but not in JIA. A recent 2008 Cochrane Review, up to October 2007, of RCTs on the effects of exercise on function, quality of life (QOL), and aerobic capacity in JIA was done. Three out of 16 identified studies met the selection criteria. Data was pooled for 212 JIA patients. The outcome measure favored a positive exercise effect but was not significant. Exercise in the excluded and included studies did not exacerbate arthritis. The author concludes that more "silver level" studies are needed to ascertain the short- and long-term effects of exercise for JIA patients (354).

**Psychosocial factors.** The disease has an impact on the child's self-image, socialization, sexuality, and integration into school activities. Efforts should be made to keep acute admissions to hospitals at a minimum so the child can participate as fully as possible in school, family, and social activities. Home schooling is not advocated. It is best to keep the child active in school. He or she should be allowed to participate as much as desired but should be given clear guidelines about limitations. Particular advice should be given in regard to sports activities. Body contact and high-impact sports are to be avoided (football, soccer, running, and ballet jumps). Cycling and swimming are to be encouraged. Guidance and support are needed during adolescence to deal with issues of vocation and sexuality. Both children and parents should be educated in the disease and the benefits of treatment. One study shows parents in an education program improved significantly concerning their self-reported competencies on medical, exercise, pain, and social support issues (355).

### Geriatric Arthritides

Care of the aged patient with arthritis is a challenge (356). Older people value the preservation of their function and independence. They are often retired or working less than full time, so that they may enjoy family, travel, and more leisure and recreational activities.

As we age, the body experiences physiologic changes of normal aging. These changes include decreased proprioception and spatial orientation, and difficulty in balancing and righting oneself, which may lead to falls. Other changes include muscle atrophy and decreased muscle power. The ability to sustain maximal muscle contraction is also reduced. The intervertebral disc becomes more desiccated. Some aged become less active and deconditioned (356). The elderly who age normally are quite functional in the community setting.

In addition to normal aging changes, many elderly have comorbid diseases (i.e., congestive heart failure, stroke, diabetes, atherosclerotic heart disease (ASHD), peripheral neuropathy, and emphysema). This necessitates the use of many medications. They have psychosocial challenges as a result of loss of job, decreased function, diminished income, and death of family members and friends, all of which lead to isolation and loneliness (357).

OA is the most common arthritis seen in the elderly. Involvement of the hips and/or knees can be associated with significant impairments and diminished function. The elderly also may have chronic RA, which had its onset earlier in life. In addition, patients 60 years or older can present with elderly-onset rheumatoid arthritis (EORA). This tends to have more equal gender distribution, higher frequency of acute systemic onset with involvement of the shoulder, a higher disease activity, and in the later stages more radiographic damage and functional decline. Efficacy and tolerability of second-line drugs is similar in both age groups, but in the elderly caution is needed with NSAIDs and prednisone (358,359).

OA coexists with RA often in the elderly. With longstanding RA or RA in combination with OA, mechanically deranged joints, ligamentous laxity, joint effusions, bursitis, and tendonitis are common. They may also have other musculoskeletal and noninflammatory disorders such as fibromyalgia, and neck and back pain syndromes. The elderly can have other inflammatory arthritides (manifested by more pulmonary and neurologic involvement than in younger patients) other than RA, including gout, pseudogout, and Sjögren's syndrome.

The elderly with arthritis tend to be less physically active. Rehabilitation treatment goals in the elderly with arthritis are to reduce impairment, functional problems, and disability by relieving pain, fatigue, and psychological stress and by improving joint motion, muscle strength, and aerobic capacity. Achieving these goals will enhance safe mobility and ADL, and help prevent disability.

Treatments, both pharmacologic and rehabilitative, need to be altered in the elderly to accommodate for physiologic aging changes in body mechanics and pharmacokinetics, the effects of comorbid diseases, and the increased presence of biomechanically deranged joints and psychosocial issues attendant to the group (360,361).

In general, exercises could include ROM, isometric, low-resistance isotonic, and low-intensity aerobic activities. Isometrics are best if ligamentous laxity and effusion are present. Precautions need to be taken with joint replacements, which are common in the elderly. Comorbid cardiac and neurologic disease also limits exercise intensity and duration.

Several RCTs show that regular exercise does not increase joint pain or accelerate disease progression. These studies suggest that exercise training may increase physiologic reserve and decrease dependency in older adults with joint disease (362). A program of progressive interval training with bicycles and step climbing in fragile elderly RA patients for 45 minutes twice a week increased work capacity 76% without increasing disease activity and has been shown to be effective (363). Heat/cold before exercise, unweighting painful lower-extremity joints, and cognitive behavioral strategies often diminish pain and improve function. Removing moderate to large joint effusions and carefully injecting any inflamed bursae or tendon sheaths also contribute to pain relief. Very painful biomechanically compromised joints that cause increased functional loss should be considered for joint replacement.

Correlates of fatigue in this population are pain severity, functional status, sleep quality, female gender, comorbid conditions, and disease duration (364). Treatment designed to decrease pain and improve sleep using short rest periods and energy conservation techniques may help reduce fatigue.

Foot problems are very common in the arthritic patient and even more common in the elderly. Proper footwear should provide a crepe sole to provide absorption of the ground reaction force, a wide base of support to promote balance, good fit with adequate depth to clear tops of toes and accommodate the width of the forefoot, and softness to relieve metatarsalgia. Foot hygiene and prompt care of skin breakdown are essential to prevent infection in a patient with possible vascular compromise of the lower extremity.

# Cardiac Rehabilitation

Although it is not as large a part of the practice of psychiatry as other areas, such as pain management or the rehabilitation of neurological disorders, cardiac rehabilitation is an area that should be a part of the scope of practice of all rehabilitation specialists. There are large numbers of patients with primary cardiac disability, and the principles of rehabilitation can be applied to their care, with energy conservation, adaptive devices, and lifestyle modifications all being part of the appropriate care of these patients. Additionally, many of the other patients who are seen in rehabilitation have underlying cardiac disabilities, and the appropriate application of cardiac rehabilitation techniques can enhance the outcomes of rehabilitation of those patients.

The goals of this chapter are to discuss the common types of cardiac disease and the principles of rehabilitation for those conditions.

## EPIDEMIOLOGY OF HEART DISEASE

### Prevalence and Incidence of Cardiac Disease

Because of the lack of activity and obesity, cardiovascular disease is a leading health care issue in the United States. Fortunately, exercise is an important and effective part of the solution to the problems we have seen above and can have profound public health benefits. As an illustration, hospital discharges for people over the age of 65 show an incidence of 767.9/10,000 for heart disease, 175.6/10,000 for cerebrovascular disease, while all cancers combined account for 172.2/10,000 population (1). The savings from even a small reduction in these numbers would be astounding, not to mention that the individual patients would be saved from illness and pain. Reviewing these numbers should provide a serious motivation to individuals to improve their own health status with a program of vigorous exercise as part of a cardiovascularly healthy lifestyle.

Despite the attention given to many other medical conditions, cardiovascular disease is still the most common cause of death and disability in the United States. Some startling statistics regarding cardiovascular health in the United States can be gleaned from the CDC reports on health behaviors of adults. The picture on leisure time physical activity is very alarming and is an area that most people can make a significant impact on their health. Despite this fact, little has been done on a national basis to engage this issue, and compliance with exercise regime remains a national concern. In the

2002 to 2004 time period, 38% of adults never engaged in any light, moderate, or vigorous physical activity, with only one in eight adults engaging in any vigorous activity at least five times a week (2). Additionally, women and older people performed less activity, and people with lower educational status and socioeconomic status were less likely to engage in physical activity. In the area of body weight, the nation has had a progressive increase in weight over the last 50 years, and in the most recent data, this trend continues (3). Overall, nearly six out of ten adults were overweight or obese in the 2002 to 2004 survey, and 23% of adults were obese. Overweight status was most common in adults between the ages of 45 and 74, being much lower for adults over 75 and under less than 45. Again, higher education was associated with a better health status, with less obesity being associated with greater education. With regard to smoking, just over a fifth of all American adults were currently smokers (4). Cigarette smoking also was associated with the onset of the disease at a younger age—four in five smokers started smoking before the age of 21. Fortunately, there is increased motivation on the part of many individuals to stop smoking, and this can help to improve the success rate.

As a rehabilitation specialist, the opportunity to intervene with your patients is especially strong, since most patients have just undergone a life-altering disability, or are seeking advice for exercise related to injuries, and may be more receptive to appropriate counseling.

### Types of Heart Disease

It is essential for a practicing psychiatrist to be familiar with the many types of heart disease that might be encountered. For practitioners of cardiac rehabilitation, post-myocardial infarction (MI) patients are most common; however, improved survival and increased availability of advanced treatments have increased the frequency of post-coronary artery bypass graft (CABG) surgery, posttransplant, heart failure, arrhythmia, and postvalvular surgery patients. The details of cardiac rehabilitation for these different populations will be discussed later in this chapter.

As noted above, the incidence of cardiac disease has been lowered due to the recognition of cardiac risk factors and interventions to prevent ischemic cardiac disease. Specifically, decreased cigarette smoking, lower red meat consumption, and increased exercise have all contributed to a decrease in coronary artery disease.

## AN OVERVIEW OF CARDIAC REHABILITATION

Currently, in the United States, only 15% to 20% of the one million survivors of acute MI go on to receive a cardiac rehabilitation program (5,6). This is an improvement over the rates of involvement of 10% to 15% a decade or so before but is still very low (7,8). Even with these low rates of participation, the cost of these cardiac rehabilitation programs was an estimated \$160 to \$240 million annually in 1990 (9), and the costs would be far higher with better participation. Cost can be reduced somewhat with the introduction of home-based programs, and there are attempts to make programs better suited for older patients. Additionally, a significant cost benefit would be realized as recent meta-analyses of the effect of the cardiac rehabilitation programs have shown that cost savings per life year gained was estimated between \$2,193 and \$28,193 and cost savings per quality adjusted life year gained was between \$668 and \$16,118 (10). These benefits are realized through decreased health care utilization and improved mortality. Cardiopulmonary conditioning and improved survival are outcomes that are well documented by numerous studies (7–10).

Simply stated, the goals of cardiac rehabilitation are to restore and improve cardiac function, reduce disability, identify and improve cardiac risk factors, and increase cardiac conditioning (11–13). These goals are achieved through the use of a prescribed exercise and education program performed under the supervision of a team composed of physicians and health professionals. The primary outcome for patients with cardiac disease is the ability to resume activities of normal life without significant cardiac symptomatology. Although the general outline of the cardiac rehabilitation program is similar for all patients with cardiac disease, specific cardiac conditions will require refinements of the exercise prescription.

## PRIMARY PREVENTION

As a rehabilitation specialist, it is essential to address lifestyle modification and education as parts of a complete cardiac rehabilitation program. Lifestyle modification is needed to address reversible cardiac risk factors, and education includes teaching patients about all cardiac risk factors. The goal is to achieve a program of cardiac risk factor modification (14). Irreversible and reversible cardiac risk factors are shown in Table 41-1. Irreversible risk factors are those that cannot be altered and include male gender, past history of vascular disease, age, and family history. Most irreversible factors are found through a thorough patient history. Where significant irreversible cardiac risk exists, early and aggressive attention to reversible risk factors becomes essential and can help to appropriately target interventions. Reversible risk factors for cardiac disease have been known for several decades and include obesity, sedentary lifestyle, hyperlipidemia, cigarette smoking, and conditions such as diabetes mellitus and hypertension (14–27). Modification of all these risk factors is an essential part of a cardiac rehabilitation program. Both patient and family education

**TABLE 41.1 Risk Factors for Coronary Artery Disease**

Irreversible Risks	Reversible Risks
Male gender	Cigarette smoking
Family history of premature CAD (before age 55 in a parent or sibling)	Hypertension
Past history of CAD	Low HDL cholesterol (<0.9 mmol/L [35 mg/dL])
Past history of occlusive peripheral vascular disease	Hypercholesterolemia (>5.20 mmol/L [200 mg/dL])
Past history of cerebrovascular disease	High lipoprotein A
Age	Abdominal obesity
	Hypertriglyceridemia (>2.8 mmol/L [250 mg/dL])
	Hyperinsulinemia
	Diabetes mellitus
	Sedentary lifestyle
	Metabolic syndrome

are necessary and can introduce lifestyle modifications as a part of the general heart healthy routine care of all family members. The rehabilitation team also needs to work closely with the primary care physician and elicit a cooperative relationship that can reemphasize the necessary lifestyle modifications. With the disabled population, this is especially important, as a risk factor of relative immobility is often present, and thus more attention needs to be paid to the other modifiable risk factors.

## REVIEW OF INDIVIDUAL RISK FACTORS

### Diabetes

Diabetes is one of the most potent risk factors for the development or reoccurrence of ischemic cardiac disease. Close control of blood sugars has been shown to decrease the risk of cardiac disease through the slowing of the development of atherosclerosis and lowering the incidence of secondary conditions such as nephrogenic hypertension (28,29). In addition to oral hypoglycemic medications and the use of insulin, a combination of exercise training, weight loss, and dietary modification can assist in improving diabetic control (30). The appropriate selection of treatments for an individual patient can be helped with following the American Diabetes Association guidelines, and early intervention can be an essential component of the prevention of later cardiac disease. The exact benefits of exercise training in combination with good glucose control are still being elucidated, but they are present. Essentially, prevention of development of a combination of diabetes, hypertension, dyslipidemia, and obesity is essential as the combination, called the multiple metabolic syndrome, can lead to increased incidence of heart disease.

## Hypertension

Establishing adequate control of blood pressure is an important part of the management of individuals with cardiac disease. Although control of hypertension has been shown to be clearly beneficial in the prevention of stroke, the data for heart disease have been more mixed. Still, it is important to control hypertension in postinfarct patients and in patients with risk for cardiac disease. Historically, blood pressure control has been shown to be most useful for patients with normal electrocardiograms (31,32).

Lifestyle modification can provide two of the most important factors in the control of hypertension: (a) reduction of salt in the diet and (b) increasing exercise to improve conditioning. Although there are many classes of pharmacological agents available for the control of hypertension, there has not been a clear benefit shown with the use of one type of agent over another except in some special situations (32). The major groups of medications for the control of hypertension are divided into beta blockers, alpha blockers, diuretics, calcium channel blockers, and ACE inhibitors. The agents that used to be believed to be most beneficial of these were the beta blockers. This is still the case in individuals with CHF, arrhythmia, hypertrophic obstructive cardiomyopathy, and prior MI. In this group of patients, these agents provide cardiac protection by decreasing the maximum cardiac oxygen consumption and through decreasing inotropy and limiting heart rate (HR) response. However, in individuals with only hypertension and no other cardiac disease, the most recent evidence indicates that there is an increased risk of stroke and no clear benefit over other agents in the prevention of cardiac disease. The current recommendations are for beta blockers not to be used as monotherapy or as a first-line agent for uncomplicated hypertension (33,34). Diuretics have been shown in large trials to have beneficial effects on decreasing mortality, especially in isolated or uncomplicated hypertension (33). Consideration needs to be made for special populations in the treatment of hypertension. For example, hypertension is more prevalent, and severe, and occurs at a younger age in African Americans (35). The issue of which agent is most effective is often not a pertinent discussion, since combination therapy is usually required to adequately control blood pressure (36). The standards for the management of hypertension are evolving rapidly, and the latest European guidelines issued in 2007 by the European Society of Hypertension and the European Society of Cardiology (ESH-ESC) (37) are likely to be incorporated in the next revision of American guidelines that are issued periodically by the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (36). The current guidelines are from 2003 and are due for revision. Since there is so much change in the management guidelines, it is recommended that rehabilitation physicians seek the advice of the treating cardiologist or internist for assistance in the optimal management of each individual patient.

## Hypercholesterolemia

Elevated levels of serum cholesterol are a modifiable risk factor that has received a great deal of attention. In the popular press

and among patients, this is the most commonly discussed risk factor. A combination of dietary modification, exercise, and medications can be very effective at controlling hypercholesterolemia. Decreased cholesterol levels and increased high density lipoprotein (HDL) have been known for a long time to be associated with decreased risk of cardiac disease (38–40). The initial approach to mild elevation of serum cholesterol is through a decrease in dietary intake of saturated fats and cholesterol, with the goal of lowering serum lipid levels, and thereby decrease cardiac risk. Even a moderate risk factor modification program can help.

Patients can decrease lipid levels by adhering to a low-cholesterol, low-fat diet along with weight reduction, even without the addition of exercise (41). Current recommendations are that the total amount of calories from fat in the diet should not exceed 30%. Control of cholesterol can be achieved through a three-step program, as outlined in the NCEP guidelines (35). Phase I is an adoption of nutritional guidelines, lifestyle changes, and general improvement in health habits. Phase II involves the addition of fiber supplements and possibly nicotinic acid. Phase III includes lipid-lowering drugs. Lipid-lowering programs have been shown to retard the progression of coronary artery disease. With the addition of physical activity, HDL cholesterol concentration can rise 5% to 16%, but the data on the lowering of low density lipoprotein (LDL) cholesterol are still controversial.

## The Metabolic Syndrome

Any current discussions of risk factor modification must involve the metabolic syndrome, which is defined by a combination of a constellation of risk factors. These risks include hypertension, abdominal obesity, dyslipidemia, and insulin resistance. The definition of metabolic syndrome was formalized by the National Cholesterol Education Program in 2001 with the requirement of the presence of three or more risk factors out of five (41) (Table 41-2). The prevalence of the syndrome from the NHANES III survey was 23.7% in 47 million individuals (42). This incidence has likely only increased since

**TABLE 41.2** Identifying Patients with the Multiple Metabolic Syndrome (Diagnosis Based on Three or More Items Being Present)

Risk Factors	Threshold Level
<i>Men and women</i>	
Fasting glucose	≥110 mg/dL
Blood pressure	≥130/85 mm Hg
Triglycerides	≥150 mg/dL
<i>Women</i>	
Abdominal obesity (measured by waist circumference)	>88 cm (>35 in.)
HDL cholesterol	<50 mg/dL
<i>Men</i>	
Abdominal obesity (measured by waist circumference)	>102 cm (>40 in.)
HDL cholesterol	<40 mg/dL

the population has continued to have increased the incidence of obesity. Presence of the metabolic syndrome is associated with a fourfold increase in fatal CHD and a twofold increase in CVD and all-cause mortality, even after adjustment for age, LDL, smoking, and family history of CHD (43); in women, it is associated with a fivefold to ninefold increase in diabetes (44,45). The major issue in the prevention of the metabolic syndrome is the control of weight gain and requires changes in a variety of behaviors, including increasing activity, decreasing sedentary activities, and reducing caloric intake. Reduction of salt intake is also essential for these individuals (46).

### Obesity

The importance of weight management has become clearer recently with the clarification of the role of central obesity in the metabolic syndrome. Weight management is an integral part of any cardiac rehabilitation program for individuals who are overweight, and there are many outside programs that can be used to help with weight management. Dietary counseling is also important, and specific counseling is based on lipoprotein levels, blood pressure, presence of diabetes or heart disease, and other risk factors. As little as a 5 lb weight loss can be associated with a 40% reduction in cardiovascular risk, according to the Framingham Heart Study (47). A 10% weight reduction can lead to a significant reduction in a number of cardiac risk factors (48). As a rehabilitation specialist, it is important to emphasize the importance of exercise and activity on the loss of weight and maintenance of target weight. The benefits of improved lipid profile and exercise have already been discussed above.

### Cigarette Smoking

Cigarette smoking is one of the greatest single modifiable risk factors for cardiac disease (49,50). There are significant benefits to smoking cessation, even as secondary prevention. Ten year mortality in individuals with angiographically demonstrated coronary artery disease or MI who stopped smoking is decreased by over 30%. Part of the mechanism of smoking induced risk is through accelerated atherosclerosis, and as a contributor to hypertension. In evaluating techniques to help with smoking cessation, exercise alone does not contribute to decreased smoking (50), and smokers tend to be less compliant in cardiac rehabilitation programs (50). However, in a program of cardiac rehabilitation coupled with counseling for smoking cessation, with appropriate medication use, a decrease in smoking has been demonstrated (50). Since smoking cessation is so critical for survival, it is essential to include cessation or enrolment in a cessation program counseling as part of a complete cardiac rehabilitation program.

## REVIEW OF CORONARY ANATOMY AND PHYSIOLOGY

In order for the rehabilitation specialist to be able to better care for individuals with cardiac disease, it is essential that a basic understanding of cardiac physiology and anatomy

be maintained. This is important for communication with cardiologists and cardiothoracic surgeons, as well as being an essential foundation that allows for better communication and education with your patients. This is not meant to be an exhaustive discussion; rather, it is a starting point from which the interested clinician can then increase his or her knowledge.

### Cardiac Anatomy

Of particular importance is a familiarity with the normal distribution of the major arteries of the heart, cardiac valvular anatomy, and the structures at risk from ischemia or infarction in these distributions. Comfort with cardiac anatomy also facilitates an informed dialogue with the referring cardiac specialists and gives the rehabilitation specialist an ability to anticipate complications and problems associated with the specific design of an exercise program specific to the patient's cardiac disease.

Overall, the heart consists of paired atria and ventricles, with deoxygenated venous blood entering the right atrium. Blood then flows into the right ventricle via the tricuspid valve and is then pumped out through the pulmonic valve into the pulmonary artery. After oxygenation in the lungs, the blood reenters the left atrium and passes through the mitral valve into the left ventricle. The left ventricle then ejects the blood through the aortic valve into the aorta and the systemic circulation. The heart valves ensure unidirectional flow of the blood, and the atria act in coordination with the ventricles to augment cardiac output (CO). Atrial contraction assists in diastolic filling of the ventricles, and can add up to 15% to 20% to the total CO. The benefits of atrial function are greater with increased HR and in conditions with decreased ventricular compliance (51). The loss of the contribution of atrial "kick" is especially important to consider in disease conditions where atrial dysfunction is seen, such as atrial fibrillation.

The cardiac conduction system is a specialized system of muscle cells (myocytes) adapted to facilitate the appropriate sequencing of the contraction of the atria and ventricles at the physiologically appropriate rate (52) (Fig. 41-1). It is a unique feature of all cardiac muscle cells that they have the intrinsic ability to contract. Additionally, myocytes are able to conduct electrical activity in order to synchronize their contractions with other cells. The usual pacemakers of the heart, with cells with the most rapid intrinsic conduction rate, are the cells of the sinoatrial (SA) node. The SA node is located in the right atrium. The electrical signal, or pulse, then travels through three atrial internodal pathways to the atrioventricular (AV) node. The AV node has a special quality of delayed conduction allowing for the sequential contraction of the atria, followed, after a short delay created by the AV node, by the contraction of the ventricles. The signal, after passing through the AV node, passes into the bundle of His, located in the intraventricular septum, which then divides further into left and right bundles. The left bundle has a final division into anterior and posterior fascicles. Terminal branches of both the right and left conduction systems carry the pulse signals that excite the myocytes, causing contraction. MI, aging, and other conditions can alter the conduction system, leading to a variety of conditions such

**FIGURE 41-1.** Schematic illustration of the conduction system of the heart with labeling of the key conduction pathways. SA node, sinoatrial node; AV node, atrioventricular node.

as heart block and sick sinus syndrome. Congenital defects and accessory tracts can lead to life-threatening arrhythmias such as the Wolff-Parkinson-White syndrome (WPW). When prescribing or supervising a program of cardiac rehabilitation, it is important for the clinician to have a good understanding of the conduction system. This knowledge is helpful in evaluating arrhythmias and assessing the risks faced by patients prior to the initiation of cardiac conditioning programs.

### Variation of Arteries

Another important part of cardiac anatomy that is important for the clinician practicing cardiac rehabilitation is the usual anatomy of the cardiac arteries. Normally, there are left and right coronary arteries arising from the base of the aorta in the left and right aortic sinuses. The left main coronary artery usually divides into the left anterior descending and the circumflex arteries, while the right coronary artery continues on as a single vessel. The standard distributions of the vessels and their rates of occurrence are seen in Table 41-3 (53). The most common anatomy of the coronary vessels is right dominant circulation, seen in 60% of individuals (see Table 41-3). When

the posterior descending artery arises from the left circumflex, as seen in 10% to 15% of individuals, this is called left dominant circulation. For approximately 30% of individuals, the posterior descending arises from the left circumflex and right coronary arteries, in what is described as balanced circulation. The anatomy and the distributions of infarcts and associated cardiac syndromes usually seen are described in Table 41-4.

### Cardiac Physiology

Cardiac myocytes are among the most metabolically active tissues in the body. In order to allow for this extremely high level of metabolic activity, oxygen extraction is nearly 65% at all levels of activity (compared to 36% for brain and 26% for the rest of the body) (54). The heart is most efficient at aerobic metabolism, but is able to perform both anaerobic and aerobic metabolism, using a variety of substrates. Carbohydrates are usually 40% of the metabolism, with fatty acids making up most of the remaining 60% metabolism (55). This high oxygen extraction and metabolism presents a relatively high risk for ischemic injury to cardiac myocytes, since coronary blood flow is only present during diastole. This is especially important for

**TABLE 41.3** Coronary Artery Anatomy

Arteries	Main Branches	Distributions	Variations
Right coronary artery	Nodal branch	Right atrium and SA node	AV node in 85%–95% of individuals, distal anastomosis to the left circumflex artery
	Right marginal branch	Right ventricle to apex	
Left coronary artery	Posterior intraventricular (descending) branch	AV node, posterior third of septum, right bundle of His	AV node in 5%–15% of individuals, 40% with some contribution
	Anterior intraventricular (descending) branch	Anterior left and right ventricles, anterior two thirds of septum, left bundle of His, AV node	
	Circumflex artery	Left atrium, superior portions of left ventricle	

**TABLE 41.4** Normal Anatomy and the Distributions of Infarcts

Anatomy of Coronary Artery	Area of Infarct	Syndrome
Left anterior descending	Anterior wall and septum	Papillary muscle necrosis Left heart failure Left ventricular aneurysm Anterior wall thrombus Conduction block
Left circumflex	Apex and lateral wall	Apical thrombus Left heart failure
Left main coronary artery	Anterior and lateral wall, apex	Massive congestive heart failure Left ventricular aneurysm Anterior wall thrombus Conduction block
Right coronary artery	Inferior wall and right ventricle	Sinus node arrest Right ventricular failure Peripheral edema

the endocardium, where increased wall tension and myocardial hypertrophy may place these myocytes at greater risk. Given the near maximum extraction of oxygen, there are only limited ways to increase oxygen supply in a situation of decreased cardiac perfusion. Under normal conditions, the coronary arteries can dilate to meet the demands of exercise. There are a number of substances secreted by the body that can increase the coronary blood flow, with nitric oxide as the final agent of many pathways (56). However, in disease vessels or situations of myocardial hypertrophy or excessive wall tension, this mechanism may not be able to allow for sufficient perfusion, and ischemia can result. Since it is so critical to restore or preserve myocardial perfusion, most medical and surgical therapies aim to restore the normal blood flow to the myocardium, either through vasodilatation or through bypass or endovascular procedures. It is also important to include exercise in the treatment regimen since regular exercise can increase cardiac collateral circulation and improve arteriolar vasodilation. These improvements are routinely seen as a result of the exercises that are a part of a cardiac rehabilitation program.

Another consideration in maximizing cardiac function is maintaining adequate venous pressures to the right side of the heart, without overloading the ventricle. The CO is in part related to increase in venous return, which increases the length of the myocardial fibers in diastole prior to the initiation of cardiac contraction. Clinicians who work with patients with cardiac disease will often refer to maintaining this filling pressure as “preload.” The benefit of myofibril stretch is to increase the overlap of the actin and myosin fibers in order to maximize the strength of contraction. However, excessive dilation of the ventricle, with further stretching in a weakened myocardium can cause the overlap of myosin and actin to decrease, yielding a decline in the strength of ventricular contraction. The relationship between the length of the fibers and the filling of the ventricle, which leads to increased contractility, is described by the Frank-Starling curve (Fig. 41-2). The clinical effects of

this overlap of myosin and actin and the resultant decreases in cardiac function are seen in both constrictive heart disease (which limits the ability to move to the right on the Frank-Starling curve) and in patients with dilated cardiomyopathies, where there is a decrease in CO due to ventricular dilation moving too far out to the right on the curve. In cases of constriction, surgery can be done to allow greater dilation of the ventricle and restoration of CO, and in dilated heart failure, therapies are directed to decrease the size of the ventricles in order to increase CO (57).

**FIGURE 41-2.** Schematic illustration of the effects of positive and negative inotropic agents on the Starling Curve, comparing cardiac output versus end diastolic volume.

In order for clinicians practicing cardiac rehabilitation to be able to discuss the basic principles of aerobic training and cardiac conditioning there is a need to have a basic understanding of the terminology and the principles of exercise physiology. These will be presented here.

## AEROBIC CAPACITY

Aerobic capacity ( $\text{VO}_{2\text{max}}$ ) is the ability of the individual to perform exercise. It is a measure of work output and is analogous in some ways to a horsepower rating of an engine. Simply viewed, it is the work capacity of an individual. Aerobic capacity can be expressed simply as the oxygen consumed (liters of oxygen per minute, or more commonly, it is expressed in milliliters of oxygen per kilogram per minute corrected for weight). Oxygen consumption ( $\text{VO}_2$ ) has a linear relationship with workload, increasing up to a plateau which occurs at the  $\text{VO}_{2\text{max}}$ .  $\text{VO}_2$  is measured through the analysis of expired gases, and for a given level of submaximal exercise,  $\text{VO}_2$  reaches steady state after approximately 3 to 6 minutes of exercise. The slope of the line between  $\text{VO}_2$  and workload represents the mechanical efficiency of the activity being performed. In conditions such as orthopedic limitations, deconditioning, or neurologic disorders, decreased efficiency is represented by an increase in the slope of  $\text{VO}_2$  and work. A useful measure is to define submaximal effort as a percentage defined by  $\text{VO}_2$  divided by  $\text{VO}_{2\text{max}}$ . The use of percent  $\text{VO}_{2\text{max}}$  allows for normalization of data across individuals and for comparison of activities.  $\text{VO}_{2\text{max}}$  has been demonstrated to decrease with age in longitudinal studies such as the Baltimore Longitudinal Study of Aging (58) (Fig. 41-3).

**FIGURE 41-3.** Schematic illustration of the plateau of oxygen consumption while workload continues to rise at maximum exercise.  $\text{VO}_2$  = work in volume of oxygen consumed.

## Heart Rate

HR is a useful measure to guide exercise as it has a linear increase in relation to  $\text{VO}_2$  or other measures of work. Maximum HR is determined by age and can be roughly estimated by subtracting the age of the individual in years from 220. The Karvonen equation is another equation to estimate peak HR and target HRs that takes resting HR into account. The slope of the line between HR and  $\text{VO}_2$  is determined by physical conditioning and the maximum HR continues to decline with age even with ongoing exercise. The physiologic regulation of HR is mediated by the interaction of vagal and sympathetic tone and circulating catecholamines (Fig. 41-4).

## Stroke Volume

Stroke volume (SV) is the quantity of blood pumped with each heartbeat. Since the heart is a muscle and strengthens with exercise, in a patient with normal myocardial function, SV can increase with exercise. During incremental exercise, SV increases the most during early exercise, with the major determinant of SV being diastolic filling time. SV is sensitive to postural changes, changing little in supine as it is near maximum at rest, while in erect position it increases in a curvilinear fashion until it reaches maximum at approximately 40% of  $\text{VO}_{2\text{max}}$  (Fig. 41-5). There is also a decreased response of SV seen with advancing age and in cardiac conditions which result in decreased compliance, such as left ventricular hypertrophy.

## Cardiac Output

CO is the product of the HR and SV. CO increases linearly with work, and in early exercise the principal increase is via

**FIGURE 41-4.** Schematic comparison of heart rate response versus workload for normal, conditioned, and deconditioned individuals.

**FIGURE 41-5.** Schematic illustration of the relationship of heart rate and stroke volume with exercise.

the Frank-Starling mechanism (SV increase), while in late exercise it is predominantly increased by HR. In general, the relationship between CO and  $\text{VO}_2$  is linear with a break in the slope at the anaerobic threshold. The anaerobic threshold

is the level of exercise at which the ability to deliver oxygen to the exercising muscles is below the demand for oxygen, marking the transition from aerobic to anaerobic metabolism. The maximum CO is the primary determinant of  $\text{VO}_{2\text{max}}$  and declines with age without any change in linearity or slope. The CO seen in submaximal work is parallel but lower in upright work compared to supine work, with  $\text{VO}_{2\text{max}}$  and maximal CO less in supine than erect positions (Fig. 41-6).

### Myocardial Oxygen Consumption

Myocardial oxygen consumption ( $\text{MVO}_2$ ) is the oxygen consumption of the heart.  $\text{MVO}_2$  rises in a linear fashion with workload. The anginal threshold is the point where  $\text{MVO}_2$  exceeds the maximum coronary artery oxygen delivery. Although  $\text{MVO}_2$  can be determined directly with cardiac catheterization, this is not practical.  $\text{MVO}_2$  is usually estimated using the rate pressure product (RPP), calculated as the product of the HR and the systolic blood pressure (SBP) divided by 100. The increase in RPP with some activities versus others explains some of the seemingly paradoxical findings in patient symptoms. For example, activities with the upper extremities and exercises with isometric components to them have a higher  $\text{MVO}_2$  for a given  $\text{VO}_2$  due to higher SBP for a given level of work. Activities performed in supine also demonstrate a higher  $\text{MVO}_2$  at low intensity and a lower  $\text{MVO}_2$  at high intensity when compared to activities performed in the erect position. Finally, the  $\text{MVO}_2$  increases for any activity when performed in the cold, after smoking, or after eating (Fig. 41-7).

**FIGURE 41-6.** Schematic comparison of cardiac output for a given workload between supine and erect exercise.  $\text{VO}_2$  = volume of oxygen consumed in mL  $\text{O}_2/\text{kg}/\text{min}$ .

**FIGURE 41-7.** Schematic comparison of myocardial oxygen consumption ( $\text{MVO}_2$ ) for a given workload for erect, supine, cold, or postprandial exercise.  $\text{VO}_2$  = volume of oxygen consumed in mL  $\text{O}_2/\text{kg}/\text{min}$ .

## AEROBIC TRAINING

Aerobic training is the term for physical exercises which are performed in order to increase the cardiopulmonary capacity ( $\text{VO}_{2\text{max}}$ ). The basic principle to effectively perform aerobic training needs to take into account four areas in prescription: intensity, duration, frequency, and specificity.

Intensity of training is defined by either the physiologic response of the individual, or the intensity of the exercise performed. For example, a program of exercises may be aimed at a target HR or RPP or at a level of exercise intensity such as the speed and incline setting for a treadmill exercise. Usually, a target heart rate is the most simple for writing exercise prescriptions for an individual. Often target HR can be set at 80% to 85% of the maximum heart rate determined on a baseline exercise tolerance test (ETT). All exercises that evoke 60% or more of the maximal heart rate will have at least some training effect.

Duration of training is essential to establish the overall conditioning. A usual cardiac conditioning exercise program is 20 to 30 minutes long, with a 5 to 10 minute warm up period before exercise, and a 5 to 10 minute cooling down period after exercise. It is usually understood that exercise at lower intensity will require a longer duration to achieve a similar training effect to exercise at higher intensity.

Frequency of training is defined as how often exercise is performed over a fixed time period, and is usually expressed in sessions per week. At a minimum, training programs should be done three times per week. With low intensity programs, an increase to five times per week may be required to offset the decreased intensity of training.

Specificity of training refers to the performance of activities in training that are the same as those desired. It is essential to remember that training benefits are most applicable to the specific activities that are performed. For example, upper extremity ergometry will not as efficiently alter the cardiac response to walking as a treadmill training program. Specificity dictates that the design of a training program needs to consider the activities and muscle groups exercise based on the needs of the particular patient, based on known vocational and recreational activities. This is often called the law of specificity of conditioning, and is commonly referred to in cardiac conditioning programs (59).

Aerobic training causes benefits in a number of physiologic parameters as discussed below (52).

**Aerobic capacity:** The maximum aerobic capacity ( $\text{VO}_{2\text{max}}$ ) of a patient will increase with training. The resting  $\text{VO}_2$  does not change, and the  $\text{VO}_2$  at a given workload does not change. The changes are also specific to the muscle groups that are trained.

**CO:** The maximum CO increases with aerobic training. The resting CO does not change, but the HR at rest will decrease, and the SV at rest will increase, leading to a lower  $\text{MVO}_2$  at rest and submaximal exercise. The CO is directly related to  $\text{VO}_2$  at rest and at a given workload, up to the anaerobic threshold. The maximum CO increases with aerobic training. The direct relationship between  $\text{VO}_2$  and CO does not change during training.

**Heart rate:** The HR after aerobic training is lower at rest and at any given workload. The maximum HR is not changed, as the maximum HR is age determined.

**Stroke volume:** The SV is increased at rest and at all levels of exercise after aerobic training. It is the increase in SV that allows for maintenance of CO at a given workload with the decrease in heart rate described above.

**Myocardial oxygen capacity:** The  $\text{MVO}_2$  response to aerobic training is the most valuable part of training in cardiac rehabilitation. The maximum  $\text{MVO}_2$  does not usually change, since it is determined by the anginal threshold. However, at any given workload, the  $\text{MVO}_2$  decreased with training. This can allow individuals to markedly increase their exercise capacity and can lead to a marked improvement in function. After training, a patient will be able to perform more activities at an  $\text{MVO}_2$  below the anginal threshold. This will lead to less symptoms and increased safety to avoid myocardial injury than before training. Pharmacological interventions or revascularization procedures can also improve maximum  $\text{MVO}_2$ .

**Peripheral resistance:** The peripheral vascular resistance (PR) decreases in response to exercise training. The PR is responsible for increases in systolic pressure and is a major contributor to myocardial wall tension, an important factor in limiting myocardial blood flow. The peripheral resistance is also often referred to by individuals involved in cardiac practice as “afterload.” The PR is decreased at rest and at all levels of exercise after a conditioning program. This response of the peripheral vasculature is due to the increased vasodilatation in peripheral vascular beds. This results in a lower RPP and a lower  $\text{MVO}_2$  at a given workload and at rest.

It is important for rehabilitation specialists working with patients with cardiac disease to remember the basic physiology described above. It is even more important to be able to describe the benefits of training to the patients so that they understand the importance of exercise as a part of their treatment regimen. The benefits of cardiac conditioning are seen in two major areas: reduced cardiac risk and improved cardiac conditioning. The reduction of cardiac risk from cardiac rehabilitation has been demonstrated in numerous studies. As examples, from as long ago as 1989, pooled data from 22 randomized studies of exercise in 4,554 patients following acute MI demonstrated a 20% to 25% reduction in all-cause mortality, fatal MI, and cardiac mortality in a 3-year follow-up (60). The benefits of cardiac rehabilitation apply to the elderly (61–63), women (64), and postbypass patients (65). Cardiac rehabilitation programs also appear to be cost effective, implying that there can be significant cost savings based on comparison with other therapies, but further studies need to be undertaken (66–69).

An easier way to explain the benefits of a cardiac conditioning program can be through the use of a table of metabolic equivalents (METs). A metabolic equivalent, or MET is the amount of energy used by an individual at rest, corresponding to the basal metabolic rate which is approximately 1 kcal/min or 3.5 mL  $\text{O}_2/\text{kg}/\text{min}$ . Remembering that at a given level of conditioning the anginal threshold is not changed but that the

**TABLE 41.5 With Sample METs**

Energy Costs of Activities of Daily Living		METs	
Sitting at rest	1	Walking 3.5 mph	3.5–4
Dressing	2–3	Walking 4 mph	5–6
Eating	1–2	Climbing up stairs	4–7
Hygiene (sitting)	1–2	Bed making	2–6

Adapted from Dafoe WA. Table of energy requirements for activities of daily living, household tasks, recreational activities, and vocational activities. In: Pashkow FJ, Dafoe WA, eds. *Clinical Cardiac Rehabilitation: A Cardiologist's Guide*. Baltimore, MD: Williams and Wilkins; 1993:359–376.

workload that can be done is increased, it is possible to see that patients with cardiac disease will be able to do more work more comfortably as their  $\text{VO}_2$  for a given heart rate increases. This greater margin of safety between the  $\text{MVO}_2$  demanded at routine activity and the anginal threshold increases both vocational and recreational activities. A sample of METs is shown in Table 41-5.

## ABNORMAL PHYSIOLOGY

It is important for effective cardiac rehabilitation to be familiar with the alterations of normal cardiac physiology in disease. Cardiac disease states generally fall into two major areas, pump failure and ischemic disease, with a degree of overlap between

the two. For example, MI will decrease the ejection fraction of the heart and thus reduce the SV and CO. Likewise, ischemic heart disease will cause the maximum heart rate to be lowered, with a resultant lowering of the  $\text{MVO}_2$  and  $\text{VO}_{2\text{max}}$  that can be achieved. During ischemic episodes, the myocardium becomes less compliant, and also less contractile, leading to a decrease in SV due to ventricular stiffening. Valvular heart disease decreases maximum CO, either through flow limitation through tight stenotic valves (e.g., aortic or mitral stenosis) or through valvular regurgitation (e.g., aortic or mitral insufficiency). The end result of the valve disease is pump failure with a decrease in  $\text{MVO}_2$  and  $\text{VO}_{2\text{max}}$  and increased  $\text{VO}_2$  at any level of submaximal exercise. Finally, congestive heart failure leads to a decreased

**TABLE 41.6** Abnormal Physiology in Response to Exercise (as Compared to Normal Individuals)

	Aerobic Capacity ( $\text{VO}_{2\text{max}}$ )	Cardiac Output	Heart Rate	Stroke Volume	Myocardial Oxygen Capacity ( $\text{MVO}_2$ )	Peripheral Resistance

×, unchanged; ↓, decreased; ↑, increased.

CO with low SV, associated with a lower  $\text{VO}_{2\text{max}}$ , higher resting HRs, and often a greater  $\text{MVO}_2$  at a given  $\text{VO}_2$ .

When present, arrhythmias usually decrease the CO through decreased SV and increased heart rates. This may be due to a loss of atrial contribution (atrial “kick”) with supraventricular arrhythmias (e.g., atrial fibrillation or supraventricular tachycardias) or through excessively high HRs without atrial coordination (e.g., ventricular tachycardias, ventricular bigeminy).

Usual surgical treatments of cardiac disease either aim to restore coronary circulation (e.g., bypass and intravascular procedures) or to restore normal anatomy (e.g., valve replacement). Medical therapy for ischemic disease aims to prevent or, if possible, improve coronary circulation, while treatment for heart failure aims to decrease afterload (reducing strain on the ventricle), reduce fluid overload (a fine balance of decreasing preload sufficiently to prevent heart failure while maintaining enough preload for ventricular function), and increase inotropy if possible. Surgical treatment of heart failure includes left ventricular assist devices (LVADs) (approved as destination devices). Medical treatment of arrhythmias with medications has been difficult, with some trials actually increasing the mortality. Implantable defibrillators and pacemakers have been the most efficient and efficacious treatment for these conditions. For intractable cases of all of these conditions, cardiac transplantation is the final possible treatment. However, rehabilitation of transplant patients also requires an understanding of the unique physiology seen in these patients. Even though the transplant may correct many of the pretransplant abnormalities such as congestive heart failure, intractable ischemia, or arrhythmia, posttransplant patients have a persistently high HR, and a limited ability to increase SV can limit exercise response. The details of a program of rehabilitation of all of these syndromes are discussed later in the chapter. The effects on the standard physiologic parameters in response to exercise, as compared to normal individuals, are seen in Table 41-6.

## CARDIAC REHABILITATION

Cardiac rehabilitation programs are generally divided into primary prevention, which includes risk factor modification and education before a cardiac event, and secondary prevention,

which is cardiac rehabilitation with exercise and risk factor modification after the establishment of cardiac disease, including MI and other conditions.

Primary prevention programs focus on the reduction of cardiac risk factors. Often this is education of patients at risk for cardiac disease and also for community-based cardiac disease prevention. The education of patients and individuals at risk for cardiac disease can have a profound effect on the rate of cardiac disease (70,71). An increase in physical activity has been shown to decrease obesity (72), lower SBP (73), and help modify lipid profiles. For behavior modification primary prevention, education about risk factor modification should begin in childhood in order to establish healthy behavior patterns to be maintained throughout life. Programs can be started in schools and parental involvement is also appropriate (74). Primary prevention can also include the use of medications for prevention of cardiovascular disease complications, and includes treatment of hypertension, lowering lipids, and antiplatelet agents. These are cost-effective approaches and large scale analyses in England and the United States that have demonstrated the cost benefits from decreased mortality and morbidity on a population-based scale, in addition to the individual benefits (75,76).

Secondary risk factor modification programs, which are the more common programs for individuals practicing cardiac rehabilitation, occur after an initial cardiac event. Secondary risk factor modification programs include all the features of the primary prevention programs with the addition of disease-specific education and formal exercise programs. The benefit in the prevention of a second cardiac event and in the reduction of mortality after MI with the initiation of risk factor modification programs has been known for over 20 years (77) and has been reemphasized in the latest guidelines (69). The lowering of blood cholesterol has been shown to be advantageous in numerous studies since the 1960s, including the Oslo Study (78), the Western Electric Study (79), the MRFIT Study (80), Helsinki Heart Study (81), National Heart, Lung and Blood Institute Type II Study (82), and others. Cessation of cigarette smoking is important, as the risk of heart disease returns to that of nonsmokers after 2 years of nonsmoking (83,84).

The control of other risk factors, such as hypertension and diabetes can also be affected by the secondary program (69).

## CARDIAC REHABILITATION OF THE POST-MI PATIENT

The actual program of cardiac rehabilitation following MI usually follows a modification of the classical model of cardiac rehabilitation as first described by Wenger et al. in 1971 (69,85). Cardiac rehabilitation is now viewed as being divided into three stages or phases. The first phase is the acute phase, which is the in hospital period immediately following the MI, leading up to discharge. This includes early mobilization. The second phase is the rehabilitation phase, which is initiated after healing is completed and is characterized by intense education and aerobic conditioning to achieve the desired results of exercise. Phase III is the final phase, which is devoted to the maintenance of the aerobic conditioning gains made in phase II, through a program of regular exercise. Risk factor modifications are taught and reemphasized throughout all phases.

### Acute Phase (Phase I)

In the classical model of cardiac rehabilitation, early mobilization was a revolutionary approach to postinfarct patients in an era when 6 weeks of bed rest was considered to be the standard of care. The basics of the early mobilization program are outlined in Table 41-7. The original program was designed to get individuals from bed rest to climbing two flights of stairs in 14 days, and modern programs achieve this goal in 3 to 5 days (69). The rapid increase in mobilization now reflects both the current drive to decrease the length of stay and the recognition of the benefits of rapid mobilization. With respect to the steps of the old program, generally patients are encouraged to be sitting out of bed and in a chair as soon as medically stable, usually by day 1 to 2 (steps 1 to 5). By day 2 to 3, short

distance ambulation can be initiated, and bathroom privileges are full (steps 6 to 9). Around day 3, the patient is introduced to the home exercise program, and stairs and increased duration of ambulation are encouraged (steps 10 to 13). After successful completion of a low level ETT for risk stratification on day 4 to 5, the patient completes learning the home program and is discharged (step 14). The educational program relating to risk factor modification should be introduced at this time, especially as many patients are ready to listen to advice in their acute hospitalization. A further modification of the classical program is that now most patients are rapidly evaluated for revascularization procedures, and often will start their rehabilitation after a catheterization or a bypass surgery. With or without revascularization, the acute mobilization should be done with cardiac monitoring (69) and under the supervision of a trained physical or occupational therapist or nurse (69). The post-MI HR rise with activity should be kept to within 20 bpm of baseline and the systolic BP rise within 20 mm Hg of baseline. Any decrease of systolic BP of 10 mm Hg or more should be considered worrisome and the exercise halted (86). The major goal of the phase I program is to condition the patient to perform activities up to four METs, which is within the range of most daily activities at home after discharge (86).

### Inpatient Rehabilitation Phase (Phase IB)

In order to distinguish between patients who have a rapid recovery after their cardiac event and after revascularization, it has been proposed that admission to either an acute or a subacute rehabilitation facility prior to discharge home be considered phase IB rehabilitation (87). This is now more commonly seen as patients with cardiac disease often are of advanced age or are suffering with comorbidities that make mobilization more difficult. It is in this stage that many rehabilitation specialists will care for these patients. The guidelines for exercise are often the same as they are for the strict phase I patients, but the period of recovery is longer.

**TABLE 41.7** Wenger Protocol

Step	Activity
1	Passive range of motion (ROM), ankle pumps, introduction to the program, self-feeding
2	As above, also dangle at side of bed
3	Active assisted ROM, sitting upright in a chair, light recreation, and use of bedside commode
4	Increased sitting time, light activities with minimal resistance, patient education
5	Light activities with moderate resistance, unlimited sitting, seated ADL activities
6	Increased resistance, walking to bathroom, standing ADL, up to 1 h long group meetings
7	Walking up to 100 ft, standing, warm-up exercises
8	Increased walking, walk down stairs (not up), continued education
9	Increased exercise program, review energy conservation, and pacing techniques
10	Increase exercises with light weights and ambulation, begin education on home exercise program
11	Increased duration of activities
12	Walk down two flights of stairs, continue to increase resistance in exercises
13	Continue activities, education and home exercise program teaching
14	Walk up and down two flights of stairs, complete instruction in home exercise program and in energy conservation and pacing techniques

**TABLE 41.8 Borg Scale**

Borg Scale	Perceived Exertion	Modified Borg Scale	
		0.0	Nothing at all
		0.5	Very, very weak
		1.0	Very weak
		1.5	
		2.0	Weak (light)
6		2.5	
7	Very, very light	3.0	Moderate
8		3.5	
9	Very light	4.0	Somewhat strong
10		4.5	
11	Fairly light	5.0	Strong (heavy effort)
12		5.5	
13	Somewhat hard	6.0	
14		6.5	
15	Hard	7.0	Very strong
16		7.5	
17	Very hard	8.0	
18		8.5	
19	Very, very hard	9.0	
20		9.5	
		10	Very, very strong
		>10	Maximal

Exercise intensity is generally limited to a target heart rate which is known to be safe. The target HR is determined either during a low level ETT or from known limitations from the revascularization performed prior to discharge to the rehabilitation setting. The level of exercise is usually done at a level of approximately 70% maximum heart rate or a MET level of 5 (69,88). For a person more than 40 years old this generally represents a maximum heart rate of 130 bpm or five METs, and for an individual less than 40 years old, 140 bpm or seven METs (50,89,90). A Borg rating of perceived exertion scale of 7 (modified scale) or 15 (old scale) can also be used to determine the maximum tolerated exercise. The Borg scale and Modified Borg scale are shown in Table 41-8. For patients at high risk, more closely monitored programs can be designed. A guideline for determining high risk during cardiac rehabilitation and the need for monitoring are included in Table 41-9.

### Training Phase (Phase II)

The training phase of the cardiac rehabilitation program is started after a symptom limited full level ETT or completion of a revascularization procedure and return to full activities. The maximum heart rate from the cardiac exercise test can be used to determine the maximum exertion during aerobic training. For patients who are in the low risk group, a program designed

**TABLE 41.9 Patients at High Risk During Cardiac Rehabilitation**

Ischemic risk
Postoperative angina
LV ejection fraction <35%
NYHA grade III or IV CHF
Ventricular tachycardia or fibrillation in the postoperative period
SBP drop of ten points or more with exercise
Excessive ventricular ectopy with exercise
Incapable of self-monitoring
Myocardial ischemia with exercise
Arrhythmic risk
Acute infarction within 6 wk
Active ischemia by angina or exercise testing
Significant left ventricular dysfunction (LVEF <30%)
History of sustained ventricular tachycardia
History of sustained life-threatening supraventricular arrhythmia
History of sudden death, not yet stabilized on medical therapy
Initial therapy of patients with automatic implantable cardioverter defibrillator (AICD)
Initial therapy of a patient with a rate adaptive cardiac pacemaker

to achieve 85% of the maximum heart rate is generally regarded as safe. For individuals who are at greater risk, exercise programs at lower target HRs can be tailored to individual patients based on the results of the ETT and the reason for cessation of exercise. Generally, for patients with life-threatening arrhythmias or chest pain, lower target HRs are chosen. In patients with higher risk, a target HR of 65% to 75% of maximum can be safe and effective in a regular exercise program (50), and target rates as low as 60% can still yield a training benefit. For the patients at higher risk, it is appropriate to monitor individuals at each increase in activity. Some guidelines for activity classification and treatment are included in Table 41-10.

A classic cardiac training program is three sessions per week for approximately 8 weeks. Unfortunately, limitations of facilities, program availability, and cost often may limit access. Even more problematic is that the majority of eligible patients are not referred to cardiac rehabilitation. This causes a potential loss of treatment efficacy and a potential increase in morbidity and mortality for patients. In order to assist in increasing access to cardiac rehabilitation, creative programs have been developed, including at home programs for low-risk post-MI patients, both community-based (91) and home-based programs (92). A key to success in home-based programs is assuring that patients are able to perform self-monitoring during their exercise program. Guidelines for self-monitoring are outlined in Table 41-11. Just as in the supervised programs, all exercise session should begin with a stretching session, followed by a warm up session, the training exercise, and end with a cool down period. It is important to remember that conditioning benefit is related to the specificity of training, and that the conditioning applies to the specific muscles exercised.

**TABLE 41.10 Activity Classification**

Activity Class	Clinical Characteristics	Activity Guidelines	ECG and BP Monitoring	Supervision Required
Class A Healthy individuals	<40 y old No known heart disease	No restrictions	None needed	None
No need for cardiac rehab program	No symptoms of heart disease Normal ETT			
Class B Known stable heart disease	NYHA class 1 or 2 Exercise capacity >6 METs	Individualized with exercise prescription by qualified personnel or restricted to walking	Only during prescriptive exercises, usually 6–12 sessions	Medical supervision during prescriptive sessions
Low risk from cardiac exercise	No clinical Heart failure			Nonmedical supervision for other exercise prescriptions
CAD	No ischemia or angina at rest or on ETT at ≤6 METs			
Valvular heart disease	Appropriate rise in BP with exercise			
Congenital heart disease	No high-grade ventricular ectopy			
Cardiomyopathy	Ability to self-monitor activity			
ETT abnormalities that are not Class C and D				
Class C Same as Class B and unable to self-regulate or monitor activity	Same as Class B except unable to self-monitor activity	Individualized with exercise prescription by qualified personnel and supervised by nonmedical personnel trained in CPR	Only during prescriptive exercises, usually 6–12 sessions	Medical supervision during prescriptive sessions
Unable to understand prescribed activity levels				Nonmedical supervision for other exercise prescriptions
Class D Moderate to high risk for complications during exercise	Two or more MI NYHA class 3 or greater Exercise capacity <6 METs	Individualized with exercise prescription by qualified personnel	Continuous during rehabilitation sessions until safety is established, usually 6–12 sessions	Medical supervision during all rehabilitation sessions until safety is established
CAD	Angina with exercise			
Valvular heart disease	Down sloping or horizontal ST depression of more than 4 mm			
Cardiomyopathy	Fall in systolic BP with exercise			
ETT abnormalities not directly related to ischemia	Life-threatening medical problems			
Previous V-Fib or sudden death not related to acute ischemia or cardiac procedure	Previous episodes of primary cardiac arrest			
High grade ventricular arrhythmias that are uncontrolled at mild to moderate work intensities	Ventricular tachycardia at loads of less than 6 METs			
Left main disease or three vessel disease				
EF <30%				

**TABLE 41.10 Activity Classification (Continued)**

Activity Class	Clinical Characteristics	Activity Guidelines	ECG and BP Monitoring	Supervision Required
Class E Unstable disease which restricts activity Unstable ischemia Uncontrolled heart failure Uncontrolled arrhythmia Severe symptomatic aortic stenosis Other conditions that can be aggravated by exercise	Unstable disease which restricts activity Unstable ischemia Uncontrolled heart failure Uncontrolled arrhythmia Severe symptomatic aortic stenosis Other conditions that can be aggravated by exercise	No activity is recommended for conditioning purposes  Try to achieve class D or better through medical management Daily activities as prescribed	No conditioning program	No conditioning program

**TABLE 41.11 Self-Monitoring Guidelines**

Patient Guidelines	Comments
Wear proper clothing	Good shoes Loose-fitting garments Garments appropriate to the ambient temperature
Follow pacing guidelines	Follow exertional guidelines established by rehabilitation team Follow perceived exertional guidelines
Follow exercise guidelines	5–10 min low intensity warm-up 20–30 min exercise at full intensity 5–10 min low intensity cool down
Stop exercising for adverse symptoms	Cardiac symptoms Chest pain Shortness of breath Lightheadedness General symptoms Joint pains Faintness with exercise
No exercise while ill	Wait for 2 d after illness has passed
No exercise in environmental extremes	Avoid extreme cold Wear warm clothing Use a face mask Exercise indoors in winter Avoid extreme heat and humidity Lower pace Exercise in air-conditioned environment Exercise early in the morning or in the evening
No exercise after eating	Wait 2 h after meals

### Maintenance Phase (Phase III)

Despite usually receiving the least attention, the maintenance phase of a cardiac conditioning program is the most important part of the program. If the patient stops exercising, the benefits gained from phase II can be lost in a few weeks. From the beginning of the cardiac rehabilitation program the importance of an ongoing exercise program needs to be emphasized throughout. In order to facilitate compliance with maintenance exercise, the program needs to integrate the actual exercises into the patient's lifestyle. There also needs to be an emphasis on secondary prevention measures and how to integrate these changes into the patient's lifestyle. For moderate level exercises, patients should be told to perform their ongoing exercises at the target heart rate for at least 30 minutes three times a week. For low-level exercise, patients need to perform exercise five times a week. ECG monitoring is not necessary during the maintenance phase.

### CARDIAC REHABILITATION PROGRAMS IN SPECIAL CONDITIONS

Due to advances in the treatment of severe cardiac disease, many more patients are being referred to cardiac rehabilitation programs. Including patients with ischemic heart disease, revascularization, heart failure, valvular heart disease, and life-threatening arrhythmias, there are now patients with LVADs and heart transplantation entering rehabilitation programs. With ongoing advances in surgical techniques, it is likely that more patients with new treatments will be referred for cardiac transplantation. In this section, we will deal briefly with all of these separate groups of patients.

**FIGURE 41-8.** Schematic illustration of the effect of conditioning level on the work level to achieve anginal threshold (anginal heart rate) among deconditioned, deconditioned, and normally conditioned individuals.

### Angina Pectoris

Cardiac rehabilitation is appropriate for patients with a stable anginal syndrome. The goal of rehabilitation in angina is to use the training effectively to improve the efficiency of exercise performance below the anginal threshold (Fig. 41-8). The benefit from exercise in angina is derived from the combination of the fact that the actual  $\text{MVO}_2$  (and thus the maximum HR) at which angina occurs will not change with conditioning, while the work done to achieve the anginal heart rate will increase substantially. Additionally, with exercise there is a possible benefit of reduction of atherosclerotic lesions and increased cardiac collateralization that is cardioprotective and symptom reducing (93–95). Before the initiation of the program of cardiac conditioning, a full level ETT should be done in order to determine the target and maximum HRs and to rule out the potential of life-threatening events. Since anginal patients have suffered no actual infarction, the rehabilitation program can begin at phase II, and the primary and/or secondary prevention program is very important. The primary goal of rehabilitation in this group of patients is aimed at increasing the work capacity. The increase in work capacity achieved will often lead to an increase in functional capacity that may significantly decrease the disability caused by their recurrent chest pain.

### Cardiac Rehabilitation After Revascularization Procedures

#### Post-Coronary Artery Bypass Grafting

There are a number of mechanisms to account for the benefits of cardiac rehabilitation in the postbypass patient which

**TABLE 41.12** Benefits of Cardiac Rehabilitation After Bypass Surgery

Increased ischemic threshold
Improved left ventricular function
Increased coronary collaterals
Ameliorated serum lipids
Decreased serum catecholamines
Decreased platelet aggregation and increased fibrinolysis
Improved psychological status

are listed in Table 41-12 (14,96). Many patients who undergo CABG or percutaneous revascularization procedures often have not had a recent MI and make excellent candidates for cardiac rehabilitation (14). Additionally, some patients have incomplete revascularization and can still be subject to ischemia, allowing them to have the same benefits from exercise seen in patients with angina. Among postrevascularization patients, patients with low ejection fractions and congestive heart failure need to be closely monitored. For these patients, the cardiac rehabilitation program has to be individualized to each patient's needs. A symptom-limited cardiac stress test can be useful in determining the level of exercise that a patient will tolerate, especially if the revascularized patient has a non-diagnostic thallium or EKG stress test. For patients who have had CABG, the exercise test can be safely performed at 3 to 4 weeks after surgery (97–99). The purpose of the exercise test is to determine the maximal functional capacity, maximal HR, exercise blood pressure response, exercise-induced arrhythmias, and anginal threshold. The initiation of a cardiac rehabilitation program also allows for the initiation of the education program to help modify risk factors. As in post-MI programs, both supervised and unsupervised home programs have been shown to be of benefit in preventing recurrent cardiac disease.

Cardiac rehabilitation after CABG can be thought of as being similar to the post-MI rehabilitation program. Phase I is the immediate postoperative period, and this is followed by a phase II training program and then phase III maintenance. The in-hospital first stage is usually in the first week or so postoperatively, as patients are usually sent home within a week. The phase I program has three stages: (a) intensive mobilization in the immediate postoperative period; (b) progressive ambulation and daily exercises; (c) discharge planning and exercise prescription for the maintenance stage (96).

Unless the patient has an unstable postoperative course, or severe heart failure, intensive mobilization begins in the intensive care unit on postoperative day 1. The program starts with sitting upright, active leg exercises, and mobilization out of bed. Early intervention has several benefits including decreasing the deleterious effects of bed rest (DVT, PE, pulmonary complications and cardiac deconditioning). The program then rapidly progresses with supervised ambulation for distances of 150 to 200 ft, advancing to most

patients beginning independent ambulation by the third day. In the last few days prior to discharge, the patient and physicians develop a program that can be self-monitored at home and allows for gradual progression to previous levels of activity.

The phase II program for a post-CABG patient is usually conducted at home or as an outpatient. High risk patients or those who need other intensive interventions may require an inpatient phase Ib rehabilitation program. This is especially true for patients who may have had a neurological or other complication from their procedure. The home and outpatient rehabilitation patients are regularly supervised by their physicians. Patients can be stratified according to risk by the criteria shown in Table 41-9. Patients usually are stratified to low, moderate, or high intensity programs depending on their level of capacity. A low-intensity program is a progressive walking program with 2 to 4 MET energy expenditures and a target HR of 65% to 75% of maximum HR. Moderate-intensity programs are usually a progressive walk to walk-jog program from 3 to 6.5 MET, with target HRs of 70% to 80% of maximum HR. High-intensity programs progress from walk-jog state to jogging from 5 to 8.5 MET with a target HR of 75% to 85% maximum HR. For patients on  $\beta$ -blockade, the target HR is usually set at 20 beats per minute above the resting HR or can be an HR determined through an ETT or exercise performed at a target MET level (100). If available, a submaximal stress test before discharge is a useful way to evaluate the physiologic response to submaximal effort and assign precautions and target exercise levels for the exercise program. Usually, exercise at a rating of perceived exertion (RPE) of 13 is a level of training that can be safely prescribed in the outpatient setting (37,39). Phase Ib programs and outpatient programs for high risk patients need to be tailored to the specific needs of the patient and designed in cooperation with the patient's cardiologist.

### Post-Percutaneous Transluminal Coronary Angioplasty

The rehabilitation of patients after percutaneous transluminal coronary angioplasty (PTCA) is essentially the same as after CABG. PTCA patients tend to be younger and have disease limited to only one or two vessels (101,102). The exercise recommendations should be similar to those for the post-CABG patient population. Cardiac rehabilitation after PTCA is easier than post-CABG since there is no significant postoperative recovery. PTCA patients can begin a conditioning and maintenance program right after their procedure. While monitoring these patients, it is important to remember that some individuals may have incomplete revascularization or may develop restenosis. As in post-CABG rehabilitation, risk factor modification training should be undertaken, and both supervised institution-based and unsupervised home programs can be undertaken. Also, just as in the group of patients after CABG, high-risk patients require closer monitoring and closer physician supervision so that institution-based programs with cardiac monitoring are advised for these individuals. For low-risk

post-PTCA patients, the recommendations in Table 41-10 can be followed.

### Cardiac Rehabilitation After Cardiac Transplant Surgery

As the techniques of orthotopic cardiac transplantation have improved, the numbers of patients with cardiac transplantation have increased. Transplant half-life (the time at which 1/2 of all transplanted patients are alive) is currently 10 years (103), and since heart transplant began on 6/30/07, there have been 76,538 heart transplants and 3,262 heart and lung transplants (104). This means that there is an increased likelihood that physiatrists will see patients who have had cardiac transplants in their practice. Typically, cardiac transplant patients are middle aged, suffer from months of preoperative invalidism and general muscle weakness, and have depression and anxiety. The transplant itself usually resolves the cardiac disability, but a comprehensive approach to the patient is necessary. Due to the complexity of the procedure and the occurrence of vascular and neurological complications, some of these patients also require phase Ib programs and may come to acute or subacute rehabilitation settings.

Because of cardiac deinnervation and immunosuppressive medications, the physiology of the posttransplant patient is somewhat different than that of the normal cardiac patient. Transplantation causes loss of cardiac innervation, with loss of both sympathetic and vagal connections to central regulation. Loss of vagal inhibition to the SA node causes the resting HR of the denervated heart to usually be near 100 bpm (105). Because there is a small SV with the resting tachycardia, the CO can be increased via the Frank-Starling mechanism with a mild increase in SV as a response to increased ventricular filling in response to light exercise. With increased exercise, circulating catecholamines induce chronotropic and inotropic responses to increase the CO (106,107). Additionally, because of loss of direct sympathetic innervation of the new heart, there is a blunted heart rate response to an incremental exercise test, with peak HRs 20% to 25% lower than in matched controls. Resting hypertension, due to the renal effects of calcineurin inhibitors (e.g., cyclosporine, tacrolimus) and prednisone, is common (108). Diastolic dysfunction is another abnormality seen after cardiac transplantation and is due to increased myocardial stiffness. There are three possible causes of the diastolic dysfunction after transplant: (a) myocardial ischemia from accelerated atherosclerosis, (b) side effect of immunosuppressive drugs, and (c) prolonged ischemic time of the donor heart (109). Finally, because transplant recipients often have a 10% to 50% loss of lean body mass from the lack of activity and high-dose steroids in the perioperative period, their maximum work output and maximum oxygen uptake are reduced to about two thirds of the age-matched population (110). This results in higher than normal perceived exertion, minute ventilation, and ventilatory equivalent for oxygen at submaximal exercise levels, while oxygen uptake is preserved, and an earlier onset of anaerobic metabolism. At maximum effort, transplant patients demonstrate lower work capacity, CO, HR, SBP, and oxygen

uptake, while resting HR and SBP are higher than in normal individuals. Finally, both resting and exertional diastolic blood pressures are higher after cardiac transplantation than in normal individuals.

Exercise testing can be performed after transplantation, but it is important to note that the donor denervated heart cannot demonstrate ischemia through anginal pain, and that close monitoring needs to be done for dyspnea, faintness, and ECG changes. In long-standing transplant recipients, accelerated atherosclerosis may develop and lead to cardiac ischemia.

The cardiac training regimen in transplant patients must address their overall conditioning and their cardiac function. Walking, jogging, cycling, and swimming are common exercises used in the program for transplant patients. In the initial postoperative period, sitting upright, lower extremity exercises, and mobilization from the bed are encouraged. The initial postoperative exercise program is similar to post-CABG patients. At the time of discharge, patients should have learned self-monitoring and are encouraged to increase ambulation as tolerated. The outpatient program then consists of progressively increasing distances for ambulation, with the pace designed to be at a level of 60% to 70% of peak effort for 30 to 60 minutes three to five times weekly (111). RPE targets, using the Borg scale, should be maintained at 13 to 14, with the level of activity increasing incrementally to stay at this level.

In addition to secondary prevention education for post-transplant patients, the rehabilitation program should also include addressing the complicated medical regimen and the vocational, debility, and psychological needs of the patient. The outcomes of rehabilitation in the cardiac transplant population have been generally favorable. Patients usually achieve increased work output and improved exercise tolerance (110), even resuming competitive athletics.

### Cardiomyopathy

With improved cardiac care, the number of patients with left ventricular ejection fraction (LVEF) of less than 30% has increased, being one of the fastest growing subsets of the cardiac rehabilitation population (112). Due to poor LV function, these patients have increased complications compared to CABG or post-MI population, with a higher risk of sudden death, depression, and chronic cardiac disability (113,114). Due to decreased CO, heart failure patients demonstrate inconsistent responses to exercise (115). One of the earliest presenting findings and causes of the functional impairment seen with CHF is due to impaired exercise capacity. The normal physiological response to exercise is often absent, and there can be a decline in ejection fraction, a decrease in SV, with resultant exertional hypotension, and syncope. In the most severe cases, CO may not increase sufficiently to generate a dynamic exercise response at all. However, the hemodynamic alterations which are seen with exercise do not always correlate with the overall exercise capacity (116), and patients

can have remarkably sustained performance with a very low LVEF. Still, low endurance and fatigue are frequently seen and prolonged postexercise fatigue is common, often lasting for hours to days after achieving a high aerobic workload (117). These limitations to exercise are often exacerbated in patients with CHF when atrial fibrillation, fluid overload, or medication noncompliance is also present. Despite these limitations, there is documented benefit from exercise in this patient population (118–120). A gradual program of increasing the HR above resting can be safe and increases the oxygen extraction efficiency. Exercise duration can increase by as much as 18% to 34% (121,122), and peak oxygen uptake can increase by 18% to 25% (121,123). The benefits of the cardiac rehabilitation programs in CHF are similar to those for angina, with lower HRs at rest and during submaximal exercise, improved anaerobic thresholds, and increased  $VO_{2max}$  (124). Since many of these patients present initially with a very low exercise capacity, even a small improvement in  $VO_2$  can mean living independently for a patient with heart failure.

Since this population of patients is at higher risk than most cardiac rehabilitation patients, it is essential to have a graded ETT before starting. Other useful baseline values can be a measurement of LVEF by multiple-gated acquisition scanning (MUGA) or echocardiography during exercise. As with cardiac rehabilitation for ischemic disease, unstable angina, decompensated CHF, and unstable arrhythmias are contraindications to cardiac rehabilitation. Due to the poor adaptation to exercise seen in CHF patients, long warm-ups and cooldown periods are required with exercise being performed with a limited workload. It is important to remember that dynamic exercise is preferable to isometric exercise, with a target HR of 10 bpm below any significant endpoint found with cardiopulmonary exercise testing, such as exertional hypotension, marked dyspnea, or sustained arrhythmia (125). Because of possible increased diastolic pressure with subsequent increase in cardiac afterload, isometric exercise should be avoided where possible and limited to 2-minute intervals for those exercises performed. It is best for cardiac exercise to be done under supervision with cardiac monitoring initially. Patients with severe left ventricular dysfunction will need telemetry during warm-up, exercise, and cooldown. Once the patient is able to self-monitor and the clinicians are confident that there are no complications during the routine cardiac exercise, patients can start a self-monitored program. Other techniques to monitor CHF patients include closely following body weight (to observe for fluid accumulation) and blood pressure and HR responses to exercise.

For more severe heart failure, including patients who are awaiting cardiac transplant due to their heart failure, management of the patient often includes pharmacologic inotropic support, and if that fails, left ventricular mechanical support. Exercise can be done on intravenous (IV) inotropes with the same caveats as for normal CHF patients (120). More recently, LVADs have become more common and are now approved

for use as a bridge for cardiac transplant or as a destination device (126–128). Any of the several models of LVAD and IV inotropes sustain cardiac function and allow mobilization of these patients. Some in-hospital acute rehabilitation units can accommodate patients who have either inotropes or LVAD in a comprehensive inpatient CR program. This facilitates earlier successful transplantation through more rapid mobilization. Centers that wish to be able to treat LVAD patients with phase Ib cardiac rehabilitation require a trained staff, close cooperation with the LVAD team, and familiarity with the devices that are used locally out of the several models now available. The most important issue for the treating rehabilitation team is to have close contact with the cardiac surgical team and to include LVAD-specific training for the patient and family. CO is typically well sustained with the device, and the patients can have good exercise tolerance. The peak capacity for exercise is often limited by the peak flow of the device, and the treating team needs to keep the patient within parameters that do not exceed the peak flow capacity of the device. Finally, drive lines need to be protected, and precautions for anticoagulation (if needed) are all part of the standard precautions.

### Valvular Heart Disease

For patients with valvular heart disease, the major issues are similar to patients with CHF or the pretransplant population. The management of the valvular heart disease patient with CHF is essentially the same as described for the CHF patient. After surgical correction of valvular heart disease, the patient improves in cardiac fitness as measured by improved oxygen consumption (129). Training can increase the physical work capacity by 60%, decrease RPE, and decrease the RPP by 15% (130). An issue that is present in many patients after valve replacement is the presence of anticoagulation postoperatively for patients with mechanical valves. When patients are on anticoagulant therapy, the exercise program has to avoid high-impact exercises to avoid hemarthrosis and bruising and include a component of education regarding injury avoidance (131). The overall training program is similar to that discussed for the post-CABG patient.

### Cardiac Arrhythmias

The risk of death from cardiac arrhythmia during rehabilitation exercises is very low. In a recent study of 25,420 patients, with 743,471 hours of exercise training, there was a risk of one myocardial arrest event for every 1.3 million therapy hours and one cardiac event for every 49,565 patient hours of exercise (132). This is an improvement in outcomes and shows the relative safety of exercise in monitored settings. Table 41-9 identifies those patients at high risk of cardiac arrhythmias who should be exercised in the monitored setting rather than in a self-directed setting at home program. For those patients with life-threatening arrhythmias, the automatic implantable cardiac defibrillator (AICD) has been used increasingly and may improve safety. The modifications for a program of

exercise with an AICD are limited and are mostly set to avoid the rate at which the device is set to fire. A prerehabilitation exercise stress test and cardiac precautions with target HR set well below the trigger threshold are sufficient modifications to the exercise program. Patients with AICD have been shown to have a good functional outcome from a rehabilitation program (133). Another important part of the rehabilitation of patients with AICD is support and reassurance about the safety of exercise, and there is a role for a cognitive-behavioral modification program for anxiety about recurrent arrhythmia (134,135).

### Cardiac Rehabilitation in the Physically Disabled

As a last note, there are some special considerations for patients with both disability and cardiac disease. Most of the difficulties in cardiac rehabilitation in this population are due to limited mobility that presents difficulty in both testing and exercise training. Patients with disability may also be at higher risk of cardiac disease, and the presence of this disease must be remembered when engaging in a rehabilitation program. Patients with stroke or peripheral vascular disease are at particularly high risk, but any patient with disability may have a cardiac comorbidity, and in cases where cardiac disease is overt, cardiac rehabilitation should be provided for these individuals just as it would be for the able-bodied population (136,137). Overall, disabled patients have several issues that place them at greater risk for cardiac disease than their nondisabled counterparts. They are usually more sedentary, which yields a higher total cholesterol and a lower HDL (138–141). Obesity occurs more frequently with disability, and deconditioning is also often seen. Additionally, disabled individuals usually require much higher energy expenditures for mobility, with a resultant need for increased work capacity.

When prescribing cardiac exercise for disabled individuals, the exercise protocols need to be adapted to the individual patient. Patients with lower extremity impairment due to neurological or orthopedic conditions perform upper extremity ergometry and modification of lower extremity exercise equipment will allow them to exercise with their legs. Hemiplegic patients can use adapted bicycle ergometers or airdynes. Since exercise protocols for stroke and other conditions incorporate upper limb exercise, the high  $\text{MVO}_2$  requirements for upper extremity exercise should be considered when designing a cardiac rehabilitation program for disabled patients. Table 41-13 shows some of the relative cardiovascular responses to arm and leg exercises. Exercise training for disabled individuals follows the same basic principles of cardiac rehabilitation for nondisabled individuals. The additional concern in disabled patients is that exercise should focus particularly on task-specific activities in order to improve aerobic conditioning and endurance, while seeking to lower  $\text{MVO}_2$  needed with each task. The physiatrist is particularly suited to take a leadership role in the area of the design of cardiac rehabilitation programs

**TABLE 41.13** Relative Cardiovascular Response to Upper (UE) and Lower (LE) Extremity Exercise

Parameter	Submaximal Exercise	Maximal Exercise
Work rate	UE = LE	UE < LE
Oxygen uptake	UE > LE	UE < LE
Cardiac output	UE > LE	UE < LE
Stroke volume	UE < LE	UE < LE
Heart rate	UE > LE	UE = LE
MVO <sub>2</sub>	UE > LE	
Systolic BP	UE > LE	UE = LE
Diastolic BP	UE > LE	UE > LE
Total peripheral resistance	UE > LE	UE > LE

for the disabled since most traditional cardiac rehabilitation programs have limited experience with the needs of physically disabled patients.

# Rehabilitation of the Patient with Respiratory Dysfunction

*The beginning of wisdom is to call things by their right names.*

Ancient Chinese Proverb

The names that are attached to clinical phenomena determine in part how they are managed. For example, “ventilator associated pneumonia (VAP)” is responsible for over 60,000 excess hospital-related deaths annually. However, no ventilator, but rather the invasive interface, causes pneumonia. If this were acknowledged, there might be a greater emphasis on providing ventilator support by noninvasive interfaces. Likewise, symptomatic respiratory acidosis due to ventilatory pump failure is generally called “respiratory” not “ventilatory” failure. If the name were more appropriate, so might be the treatment, that is, assisted ventilation rather than supplemental oxygen. Many patients we treat must be “habilitated” rather than “rehabilitated.” This brings us to the definition of “pulmonary rehabilitation.”

Pulmonary rehabilitation has been defined as “a multidimensional continuum of services directed to persons with pulmonary disease and their families, usually by an interdisciplinary team of specialists, with the goal of achieving and maintaining the individual’s maximum level of independence and functioning in the community” (1). Interventions can include exercise, respiratory muscle rest and support, education, emotional support, oxygen, airway secretion clearance, promoting compliance with medical care, facilitating return to work, and a more active and emotionally satisfying life. These goals are appropriate for any patients with diminished respiratory reserve whether due to obstructive or intrinsic pulmonary diseases (oxygenation impairment) or neuromuscular weakness (ventilatory impairment). The former are normally eucapnic or hypocapnic, often despite severe hypoxia, and hypercapnia occurs only during episodes of acute respiratory failure (ARF) or with end-stage disease. For the latter, hypercapnia begins during sleep and precedes significant hypoxia or oxyhemoglobin desaturation. The *ventilatory dysfunction* causes decreased blood oxygenation. Many useful techniques for managing the latter were described, developed, or initially adapted by physiatrists in the United States (2–7), and elsewhere (8).

## REHABILITATION OF PATIENTS WITH OBSTRUCTIVE LUNG DISEASE

Thirty-two sources of chronic obstructive pulmonary disease (COPD) prevalence estimation rates from 17 countries were surveyed. Prevalence ranged from 0.23% to 18.3%. In Europe and North America, rates were between 4% and 10% (9). COPD is the second most common noninfectious disease in the world, causing 2.75 million deaths annually with global mortality predicted to double by 2030. It is the fourth largest cause of major activity limitation (10). Thirty percent of COPD patients with forced expiratory volume in 1 second (FEV<sub>1</sub>) less than 750 milliliters (mL) and 35% following an acute exacerbation die within 1 year (11) and 50% within 3 years (12).

### Patient Evaluation

In addition to the elements of the patient evaluation noted in Table 42-1, any medical, physical, financial, or psychological factors that might interfere with a rehabilitation program need to be addressed (12). Commonly overlooked is the fact that 13% of COPD patients are anemic. This may indicate presence of erythropoietin resistance and be associated with increased serum inflammatory proteins (13).

Various dyspnea assessment surveys can be used to objectify the extent of dyspnea and the effects of rehabilitation (14–17). In addition, the presence of any dyspnea, coughing, wheezing, chest pains, neurologic or psychological disturbances, allergies, previous communicable diseases, injuries, and nutritional imbalance is explored.

Poor nutrition can be characterized by low protein values. Other tests that assess nutritional status include total iron binding capacity, cholesterol, and serum vitamin levels, especially of vitamins A, C, and E. This is especially important because COPD and neuromuscular disease (NMD) patients have a high incidence of vitamin deficiencies. Delayed cutaneous hypersensitivity is a function of cell-mediated immunity and is the immune response most sensitive to nutritional deprivation. Hypophosphatemia, hypomagnesemia, hypocalcemia, and hypokalemia may also cause respiratory muscle weakness, which is reversible following replacement (18). Social, educational, and vocational histories and any relevant environmental factors are explored.

**TABLE 42.1 Patient Evaluation**

Family history of pulmonary diseases
Symptom progression and impact on function
Exacerbation and hospitalization history
Appetite, nutritional status, and weight changes
Medications, substance abuse
Physical examination for hyper-resonant chest, poor breath, and cardiac sounds
Hemoglobin/hematocrit, sedimentation rate, C-reactive protein, white cell count
Radiographic assessment of (low, flattened) diaphragm, (long, narrow) heart shadow, retrosternal translucency, narrowing of peripheral pulmonary vessels
PaCO <sub>2</sub> and PaO <sub>2</sub> and diffusion capacities (decreased in emphysema, normal in bronchitis)
Pulmonary function tests for air and mucus trapping
Low-maximum midexpiratory flow rates and increased midexpiratory times, normal or increased lung compliance and increased flow work, increased residual volume and total lung capacity
Clinical exercise testing
A 3-, 6-, or 12-min walk
Assessment of the VAT and maximum exercise tolerance for a precise exercise regimen

The pulmonary function studies of COPD patients demonstrate air trapping, low-maximum midexpiratory flow rates and increased midexpiratory times, normal or increased lung compliance, and increased flow work. Residual volume and total lung capacity are generally increased. Exertional dyspnea tends to occur when the forced expiratory volume in 1 second (FEV<sub>1</sub>) is less than 1,500 mL. FEV<sub>1</sub> decreases by 45 to 75 mL/yr for COPD patients (19), a rate up to three times normal. Arterial oxygen tensions may be posturally related, significantly decreased with the patient supine (20), and desaturation may be episodically severe during sleep (21).

Since pulmonary function impairment does not predict the overall functional impairment, clinical exercise testing is done. This measures the functional reserve of all mechanisms taking part in oxygen and carbon dioxide transport and yields information regarding the capacity to perform exercise, the factors that limit exercise, the reasons for exercise-related symptoms, and the diagnosis (22). It permits the clinician to determine whether the primary disability is pulmonary, cardiac, or related to exercise-induced bronchospasm (23). The latter two diagnoses and even the presence of purely restrictive pulmonary syndromes are commonly mistaken for COPD and, therefore, may be mismanaged. Clinical exercise testing can also be useful for documenting patient progress with rehabilitation.

Clinical exercise testing, whether by using a treadmill, stationary bicycle, or upper-extremity ergometer, includes monitoring of: vital signs, electrocardiography, oxygen consumption, carbon dioxide production, the respiratory quotient, the ventilatory equivalent, minute ventilation, and metabolic rate. The respiratory quotient is the ratio of the carbon dioxide produced divided by the oxygen consumed. The ventilatory equivalent

is equal to the volume of air breathed for 1 L of oxygen consumed. A metabolic equivalent (MET) is the resting metabolic rate per kilogram of body weight (i.e., 1 MET = 3.5 mL O<sub>2</sub>/kg/min). Other useful measures for noninvasively assessing cardiac function include the oxygen pulse, a measure of the mL of oxygen consumed per heart beat (23). A clinical exercise test should advance until oxygen consumption fails to increase, maximum allowable heart rate for age is reached (usually 220—age in years), or electrocardiographic changes, chest pain, severe dyspnea, or intolerable fatigue occurs. A minute ventilation 37.5 times the patient's FEV<sub>1</sub> can be the goal (24). Arterial blood gases may be normal at rest but are often abnormal during exercise. Oximetry is performed to determine need for supplemental oxygen therapy to maintain SpO<sub>2</sub> greater than 90% during reconditioning exercise or greater than 60 mm Hg long term (25). It has been suggested that supplemental oxygen benefits patients with COPD with moderate-to-severe airflow obstruction and mild hypoxemia at rest by improving exercise tolerance and reducing pulmonary hypertension during exercise (26).

When energy cost studies are not available, maximum exercise tolerance may be estimated from pulmonary function data (27). A 3-, 6-, or 12-minute walk test can also provide useful information. The patient is instructed to gradually increase walking speed and duration on subsequent walking tests. The test is simple and may be performed daily in the hospital or at home (28).

Any motivated COPD patient who has respiratory symptoms that limit activities of daily living (ADL) and who has adequate medical, neuromusculoskeletal, financial, and psychosocial status to permit active participation is a candidate for rehabilitation. Active patients who are still able to walk several blocks but who have noted yearly decreases in exercise tolerance or who have recently begun to require ongoing medical attention for pulmonary symptoms or complications are ideal candidates.

### Organization of a Comprehensive Rehabilitation Program

Because, other than perhaps for smoking cessation (29,30), there is no evidence that inpatient programs are more effective than outpatient programs (29–32), the former should be reserved for severely debilitated patients (33), for tracheostomy tube removal or for optimizing the ventilatory aid regimen while initiating other aspects of comprehensive rehabilitation (34). Table 42-2 is a sample therapeutic prescription for an ambulatory, moderately affected COPD patient.

### Therapeutic Interventions Medications

The patient's medical regimen is optimized prior to reconditioning exercise. Bronchodilators are delivered as aerosolized solutions but are not effective if the patient deposits the medications uselessly on the tongue. COPD patients require training in the use of “spacers” and nebulizers (35). Orally administered  $\beta$  agonists are used when aerosolized medications are ineffective or when metered-dose inhaler cannot be

**TABLE 42.2 A Sample Therapeutic Prescription for a Patient with COPD**

*Diagnosis*

Chronic obstructive pulmonary disease

*Prognosis*

Favorable, patient on stable self-medication program

*Goals*

- Ease sleep disordered breathing and rest inspiratory muscles
- Improve endurance and efficiency
- Optimize oxygen needs and control of secretions
- Increase independence in ambulation and self-care activities
- Reduce anxiety and improve self-esteem through enhanced body awareness

*Precautions*

- Supplemental oxygen needed during exercise
- Discontinue and notify physician if patient becomes severely dyspneic or develops chest pain with exercise

*Respiratory therapy*

- Conduct ear oximetry at rest and during exercise to determine portable oxygen flow rate needed to maintain oxygen saturation higher than 90%
- Instruct patient in diaphragmatic and pursed-lip breathing
- Instruct patient and family in postural drainage techniques
- Instruct patient and family in portable oxygen use
- Instruct in use of metered-dose inhaler before exercise
- Instruct in use of nocturnal BiPAP

*Physical therapy*

- Assess baseline endurance, using 12-min walk test
- Begin incremental exercise program to improve endurance through ambulation and stair climbing. Begin with 5-min sessions, followed by rest periods between sessions. When patient tolerates 20 min of total exercise per day, begin consolidating the sessions. Initial treatments on daily basis during weeks 1 and 2, taper to three times per week over weeks 3 and 4, and then taper to home program with self-monitoring in weeks 5 and 6.
- Review proper body mechanics and coordinate with breathing patterns, using diaphragmatic and pursed-lip breathing when appropriate

*Occupational therapy*

- Assess upper-extremity mobility, strength, and endurance
- Evaluate basic and advanced self-care activities, and provide adaptive aids to improve independence with dressing, hygiene, bathing, cooking, and other chores
- Train the patient in energy conservation and work simplification techniques
- Evaluate home environment and make recommendations for workspace modifications and equipment to improve safety, efficiency, and independence
- Provide relaxation exercise training with visual imagery techniques

efficiently used. One half to two thirds of 33 double-blind, randomized, placebo-controlled studies showed significant positive effects of anticholinergics and short-acting  $\beta$ -2 mimetics (especially salbutamol), respectively, on exercise capacity.

Early medical attention is important during intercurrent respiratory tract infections (36). Antibiotics, glucocorticoids, and adjustment of bronchodilators and mucolytic agents may be indicated. *N*-acetylcysteine at 1,200 mg/d was demonstrated in a randomized, double-blind, placebo-controlled study to normalize C-reactive protein levels, lung function, and symptoms during acute exacerbations and possibly in preventing the exacerbation (37).

### Counseling and General Medical Care

Dyspnea often causes fear and panic. This may worsen tachypnea while increasing dead-space ventilation, the work of breathing, hyperinflation, and air trapping. Relaxation

exercises, such as Jacobson exercises and biofeedback (38,39), yoga, and diaphragmatic and pursed-lip breathing, can be used to decrease tension and anxiety.

COPD patients perceive impairment in quality of life. Depression has been reported in 50% of patients, and there is often severe reduction in social interaction (40). Integrating psychosocial support with multimodal pulmonary rehabilitation optimizes intervention (41). Loss of employment and physical independence may also need to be addressed.

COPD patients tend to overuse medications during periods of respiratory distress and underuse them otherwise. They are counseled on adhering to their medication regimens (42), and on avoiding atmospheric or vocational pollutants and other aggravating factors, such as pollen, aerosols, excessive humidity, stress, and respiratory tract pathogens. Yearly flu vaccinations are recommended; and pneumococcal vaccines are used one time or every 5 to 10 years for high-risk cases.

High-altitude travel may require an additional 0.5 L/min of supplemental oxygen administration for those already requiring supplemental oxygen; otherwise, oxygen therapy generally need not be used for short flights (43). Good hydration should be maintained with ample fluid intake.

### Nutrition

Significant weight loss occurs in 19% to 71% of COPD patients (18). In a study of 255 stable COPD pulmonary rehabilitation patients, depletion of body weight, fat-free mass, and muscle mass was noted in 40% to 50% of patients with chronic hypoxemia and in normoxemic patients with  $FEV_1 < 35\%$  (44). In one study, 30 of 50 consecutive COPD patients presenting with ARF were significantly undernourished, and impaired nutritional status was more prevalent in those patients requiring mechanical ventilation (74% vs. 43%) (45).

Undernutrition has been associated with an increased susceptibility to infection that is due in part to impaired cell-mediated immunity, reduced secretory immunoglobulin A, depressed pulmonary alveolar macrophage function, and increased colonization and adherence of bacteria in the upper and lower airways. Patients with significant nutritional impairment are more frequently colonized by *Pseudomonas* species (46,47). In addition, malnutrition can adversely affect lung repair, surfactant synthesis, control of ventilation and response to hypoxia, respiratory muscle function and lung mechanics (48), and water homeostasis. It can lead to respiratory muscle atrophy and decreased exercise capacity, cor pulmonale, increased rate of hospitalization for pulmonary-related problems, hypercapnic respiratory failure, and difficulty in weaning from mechanical ventilation (45,49,50). Likewise, inappropriate nutrition, such as increasing carbohydrate intake, can exacerbate hypercapnia.

Short-term refeeding of malnourished patients can improve respiratory muscle endurance and increase respiratory muscle strength in the absence of demonstrable changes in skeletal muscle function (51). Because of bloating due to a low diaphragm, patients are advised to take small mouthfuls of food, eat slowly, and take smaller and more frequent meals.  $SpO_2$  can be evaluated while eating. If desaturation occurs, supplemental oxygen is used or increased. For those with hypercapnia, a dietary regimen high in calories derived from fat can decrease hypercapnia. Although short-term refeeding can be beneficial, refeeding programs lasting more than 2 weeks have not consistently resulted in increases in body weight. Growth hormone has not been shown to be useful. Possible beneficial effects of anabolic steroids as adjuncts to nutritional support and exercise have been reported to increase lean body mass and promote weight gain (52–54).

### Breathing Retraining

Shallow, rapid breathing is commonly seen in anxious, dyspneic patients. This increases dead-space ventilation and airflow through narrowed airways, increasing the flow work of breathing. Patients with chronic airflow obstruction also have an altered pattern of ventilatory muscle recruitment in which

the most effective ventilatory pressure is generated by the rib-cage inspiratory muscles rather than by the diaphragm, with significant contribution by primarily expiratory muscles (55). Diaphragmatic breathing and pursed-lip exhalation can help to reverse these tendencies. These techniques are usually initiated in the supine or 15% to 25% head-down position. Diaphragmatic breathing is guided by having the patient place one hand over the abdomen and the other on the thorax just below the clavicle. Breathing deeply through the nose, the abdomen is distended forward as appreciated by movement of the hand on the abdomen. Movement of the rib cage and, thus, the hand on the thorax should be kept to a minimum. Small weights can be placed on the abdomen to provide some resistance training and enhance the patient's focus. During exhalation, the abdominal muscles and the hand on the abdomen compress the abdominal contents, and exhalation is via pursed lips (56). Classically, a lighted candle is put several feet in front of the patient, and the patient flickers the flame while exhaling. This equalizes pleural and bronchial pressures, preventing collapse of smaller bronchi and decreasing air trapping. Diaphragmatic and pursed-lip breathing decreases the respiratory rate, coordinates the breathing pattern, and can improve blood gases (57). It is used during routine ADL and exercise. It can improve exercise performance by relaxing accessory muscles and improving breathing efficiency.

Air-shifting techniques may be useful to decrease microatelectasis. Air shifting involves taking a deep inspiration that is held with the glottis closed for 5 seconds, during which time the air shifts to lesser-ventilated areas of the lung. Expiration is via pursed lips. This technique may be most beneficial when performed several times per hour.

### Airway Secretion Elimination

Airway secretion clearance is crucial because exacerbations of COPD are caused by trapping of airway secretions in the peripheral airways. The patient's cough may be weak or ineffective as a result of increased airway collapse in more central airways, and frequent bouts of coughing are fatiguing. The high expulsive pressures generated during coughing can exacerbate both air trapping and secretion retention. "Huffing," or frequent short expulsive bursts following a deep breath, is often an effective and more comfortable alternative to coughing. Chest percussion and postural drainage can be useful for patients with chronic bronchitis or others with greater than 30 mL of sputum production per day (58), although caution must be taken to increase oxygen delivery as necessary during treatment. Autogenic drainage involves breathing with low tidal volumes between the functional residual capacity and the residual volume to mobilize secretions in small airways. This is followed by taking increasingly larger tidal volumes and forced expirations to transport mucus to the mouth (59).

Application of positive expiratory pressure (PEP) breathing is based on the theory that mucus in small airways is more effectively mobilized by coughing or forced expirations

if alveolar pressure and volume behind mucous plugs are increased. PEP is applied by breathing through a face mask or a mouthpiece with an inspiratory tube containing a one-way valve and an expiratory tube having variable expiratory resistance. Expiratory pressures of 10 to 20 cm H<sub>2</sub>O are maintained throughout expiration. PEP increases functional residual capacity, reducing resistance to airflow in collateral and small airways (60,61). Studies on the clinical benefits of PEP breathing have been inconclusive for both cystic fibrosis (CF) and COPD (62–70).

Flutter breathing is a combination of PEP and oscillation applied at the mouth. The patient expires through a small pipe. A small stainless steel ball rests on the expiratory end of the pipe; it is pushed upward during expiration, producing PEP, and falls downward again, interrupting flow. The mucus-mobilizing effect is thought to be due to widening of the airways because of the increased expiratory pressure and airflow oscillations due to the oscillating ball (71). For this too, however, the results of clinical trials have been conflicting (72–76).

With currently available technology, mechanical vibration or oscillation can be mechanically applied to the thorax or directly to the airway to facilitate airway secretion elimination. Vibration is possible at frequencies up to 170 Hz applied under a soft plastic shell to the thorax and abdomen (the Hayek Oscillator, Breasy Medical Equipment Inc., Stamford, CT). Another device delivers rapid burst airflows at up to 25 Hz under a vest covering the chest and upper abdomen (THAIRapy System, American Biosystems, Inc., St. Paul, MN). The effects of mechanical chest percussion and vibration appear to be frequency dependent (77–79). In most animal studies, frequencies between 10 and 15 Hz appear to best facilitate mucous transport (77,79,80), especially the transport of a thicker mucous layer (81). Warwick and Hansen found long-term increases in forced vital capacity (FVC) and forced expiratory flows for CF patients treated with high-frequency chest-wall compression as compared with manual

chest percussion alone (82). Others have reported improvement in pulmonary function and in gas exchange during high-frequency oscillation (83–87), and Sibuya et al. found that chest-wall vibration decreased dyspnea (86). Most studies on COPD and CF patients, however, have failed to demonstrate objective clinical benefits from percussion or vibration on mucous transport (87–90). Side effects of percussion and vibration can include increasing obstruction to airflow (91,92). In an animal model, the application of vibration and percussion was also associated with the development of atelectasis (93). Despite conflicting studies, the THAIRapy Vest has become popular for CF and familial dysautonomia patients, and studies have claimed decreases in hospitalization rates with its daily use (77). Patients with daily airways secretion encumbrance usually feel that its use is beneficial.

The Percussionator (Percussionaire Corp., Sandpoint, ID) can deliver aerosolized medications while providing high-flow percussive minibursts of air directly to the airways at rates of 2.5 to 5 Hz. This intrapulmonary percussive ventilation has been reported to be more effective than chest percussion and postural drainage in the treatment of postoperative atelectasis and secretion mobilization in COPD patients (94,95). The majority of such patients feel that it is helpful (96,97).

Patterson et al. found in a 10-year study that good CF patient compliance with airway secretion mobilization methods was associated with a slower rate of loss of pulmonary function (98). Patient compliance is usually poor, however (99–101). There is greater patient compliance for simple methods that can be used independently. Little has been documented concerning long-term safety and efficacy of any of these methods. Because expensive methods have not been shown to be more effective than simple handheld percussors costing about \$400 (Jeannie Rub Percussor, Morfan Inc., Mishawaka, IN [Fig. 42-1] or NeoCussor General Physical Therapy, St. Louis, MO), the latter should be favored for routine clinical use.

### Inspiratory Resistive Exercises

Inspiratory resistive exercises, including maximum sustained ventilation, inspiratory resistive loading, and inspiratory threshold loading, can improve the endurance of respiratory muscles (102–104). Typically, patients breathe through these devices for a total of 30 minutes daily for 8 to 10 weeks. The settings of the devices are adjusted to increase difficulty as patients improve and the program advances.

Levine et al. conducted an evaluation of the isocapnic hyperpnea method and determined that no more benefits could be derived from it than could be achieved using periodic intermittent positive pressure breathing treatments, a regimen that was considered equivalent to placebo (105). However, Ries and Moser randomly assigned 18 patients to either a home isocapnic hyperventilation training program or a walking program and found that the former led to improvements in ventilatory muscle endurance and exercise performance and significant improvements in the maximum rate of oxygen consumption ( $\text{VO}_{2\text{max}}$ ), whereas walking exercises improved lower limb exercise endurance but not ventilatory muscle endurance (106).

Twenty-one controlled studies of inspiratory resistive loading involving 259 COPD patients reported improvements in inspiratory muscle strength and endurance (107). The mean increase in maximum inspiratory pressure was 19%. However, the subjects using inspiratory resistance training reduce their inspiratory flow rates and lengthened their inspiratory time to reduce the severity of the imposed loads. Thus, “targeted” or threshold inspiratory muscle training is recommended over flow-resistive training to assure adequate intensity of inspiratory muscle activity.

With targeted training, the subject is provided feedback regarding the inspiratory flow rates through the resistor or the inspiratory pressure generated by flow through the resistor; with threshold training, the subject is unable to generate flow through the device until a predetermined pressure is achieved. Six of the nine controlled studies of the use of targeted or threshold resistor devices in COPD reported significantly greater improvements in inspiratory muscle function in the subjects than in the controls (107). In three of the six studies in which it was assessed, exercise tolerance was greater for trained subjects than for controls. In one controlled study comparing exercise reconditioning plus threshold inspiratory muscle training with exercise reconditioning alone, the former resulted in significantly greater increases in inspiratory muscle strength and endurance and in exercise tolerance (108). Exercise tolerance seemed to be improved particularly for those with electromyographic changes indicating inspiratory muscle fatigue with exercise (109). One controlled, well-designed, but small study of threshold inspiratory exercise for CF patients demonstrated significant improvements in inspiratory muscle strength, FVC, total lung capacity, and exercise tolerance in the experimental group (110). In another controlled study of patients taking corticosteroids, inspiratory muscle training appeared to prevent the weakness that would have otherwise resulted from the steroid use (111). The combination of inspiratory muscle training along with

bronchodilator therapy and reconditioning exercise was demonstrated to very significantly reduce dyspnea by comparison to the use of bronchodilators and general exercise without inspiratory muscle training (112). A recent study showed benefit incorporating inspiratory muscle training into a pulmonary rehabilitation program (113). In general, improvements in inspiratory muscle function and in exercise tolerance were greater for the targeted and threshold studies than for the flow-resistor studies (114).

### Respiratory Muscle Rest

Relatively minor changes in the pattern of breathing or respiratory muscle loading can trigger acute respiratory muscle fatigue and failure. Interspersing periods of exercise and muscle rest is a basic principle of rehabilitation. Hypercapnia is an indication of limited reserve before the appearance of overt fatigue and may indicate the need for periods of respiratory muscle assistance or rest before considering strengthening exercises (115). Diaphragm rest can be achieved by assisted ventilation using either body ventilators, mouth piece, or nasal noninvasive positive pressure ventilation (NIV).

Despite high ventilation rates in COPD, ventilatory response to both hypercapnia and hypoxia may be reduced. This is often exacerbated during sleep. The increase in pulmonary vascular resistance that occurs in the presence of pulmonary tissue hypoxia is exacerbated by acidosis. When this situation becomes severe, it may lead to right ventricular failure. The use of oxygen therapy alone may exacerbate  $\text{CO}_2$  retention and acidosis.

Two groups of patients may be suited to ventilatory assistance at home. The first and smaller group includes those who use ventilatory assistance around the clock, usually by tracheostomy, but who are medically and psychologically stable. These patients tend to require frequent hospital readmission, have a poorer prognosis than ventilator-assisted individuals with NMD, and can be candidates for decannulation to NIV. The second group may benefit from nocturnal assistance alone.

While both nocturnal negative pressure body ventilator (NPBV) use and NIV can normalize arterial blood gases, and have been reported to increase quality of life, 12-minute walking distance, respiratory muscle endurance, and decrease dyspnea (116), the former methods cause obstructive apneas during sleep (117,118). The NIV methods, provided by portable ventilators and bilevel positive airway pressure (BiPAP) machines, can rest inspiratory muscles, assist ventilation, and splint open the airway to prevent sleep apneas and airway collapse (119).

Belman et al. reported greater diaphragm relaxation by nasal ventilation than by use of NPBVs (120). Marino demonstrated reversal of nocturnal ventilatory insufficiency for COPD patients using nasal ventilation (121), and others have used assisted ventilation via oral-nasal interfaces as an alternative to intubation and tracheostomy for COPD patients in acute exacerbation (122). Nasal BiPAP has the additional benefit of the expiratory positive airway pressure countering auto-positive end-expiratory pressure (PEEP) in these patients

who trap air. This decreases their work of breathing. A number of studies have reported long-term improvements in daytime blood gases with the use of nocturnal nasal ventilation for hypercapnic COPD patients (116,123,124), and it has been suggested that nocturnal ventilator use can also decrease dyspnea, improve quality of life (125), and improve survival (123). Nocturnal nasal BiPAP was also reported to improve sleep efficiency and total sleep time in hypercapnic COPD patients (126). In another study of 49 hypercapnic patients with COPD, while hospitalization rates were decreased by both long-term oxygen therapy (LTOT) and by LTOT with nocturnal nasal ventilation by BiPAP, only the latter group had a significant decrease in intensive-care admissions and a significant improvement in 6-minute walk distance (127). However, a systematic review (76) of nocturnal noninvasive positive pressure ventilation of at least 3 months duration in stable hypercapnic COPD patients did not find a consistent clinically or statistically significant effect on lung function, gas exchange, respiratory muscle strength, sleep efficiency, or exercise tolerance. However, these conclusions are limited by the small size of the underlying studies. Although it is widely considered appropriate to offer nocturnal BiPAP for hypercapnic COPD patients, little or no benefit has been reported with nocturnal use for nonhypercapnic patients for whom its role remains controversial (128). Use of proportional assist ventilation and pressure support during exercise has been reported to facilitate high-intensity exercise training in severe COPD (129–131). Patients benefiting from proportional assist ventilation were reported to achieve 15% higher exercise levels at 6 weeks than those exercising without it. Users had a significant reduction in plasma lactate concentration at equivalent workloads after training.

### Supplemental Oxygen Therapy

Supplemental oxygen therapy is indicated for patients with  $pO_2$  continuously less than 55 to 60 mm Hg (132). Home oxygen therapy can decrease pulmonary hypertension, polycythemia, and perception of effort during exercise, and it can prolong life (132,133). Patients with COPD have also been shown to have increased sympathetic modulation and reduced baroreflex sensitivity. Supplemental oxygen has been shown to significantly and favorably alter autonomic modulation and decrease blood pressure and pulse (134). In addition, cognitive function can be improved, or at least, better maintained, and hospital needs reduced.

An international consensus on the current status and indications for LTOT suggested that the prescription be based on (135):

1. An appropriately documented diagnosis
2. Concurrent optimal use of other rehabilitative approaches, such as pharmacotherapy, smoking abstinence, and exercise training
3. Properly documented chronic hypoxemia

Oxygen therapy should be given with caution to hypercapnic patients whether or not they are using NIV (136).

There can also be need for supplemental oxygen during exercise. Many patients exhibit exercise hypoxemia. Decreases in  $SpO_2$  are noted at physical activity levels comparable to those necessary to perform ADL. Often, the decrease in  $SpO_2$  occurs within the first minute, after which  $SpO_2$  stabilizes; but occasionally there is a progressive decline in  $SpO_2$  with exercise. In a study of 38 subjects in whom the mean resting  $SpO_2$  was  $93 \pm 3\%$ , a decrease in  $SpO_2$  of  $4.7 \pm 3.6\%$  (range: 1% to 18%) was observed during submaximal exercise (137).

In a crossover study of 12 subjects with severe COPD (138), four patients more than doubled their duration of exercise while receiving 40% oxygen, but in only two of these was desaturation observed in the absence of oxygen. Bradley et al. reported that in subjects with mild hypoxemia and exercise desaturation, supplemental oxygen by nasal prongs did not influence maximum work rate but did influence endurance (139). Davidson et al. noted that oxygen increased mean walking endurance time by 59% and 6-minute walking distance by 17%. Moreover, submaximal cycle time at a constant workload was increased by 51% at a flow rate of 2 L/m and by 88% at 4 L/m, suggesting a dose-response curve (140). The exercise response to oxygen could not be predicted from the degree of desaturation, resting pulmonary function tests, echocardiographic measurements of right ventricular systolic pressure, or other clinical parameters (138). In fact, in nonhypoxemic COPD patients performing moderate exercise, oxygen supplementation decreases ventilatory requirement by its direct effect on chemoreceptor inhibition (141). Thus, exercise tolerance can be increased by oxygen therapy without improving oxygen consumption or utilization. A recent study found that supplemental oxygen during exercise prevented exercise induced oxidative stress (142). Marcus et al. also reported significantly greater exercise tolerance in CF patients receiving oxygen (143). A recent study found improved exercise tolerance in CF patients in the Dead Sea basin compared with at sea level (144). This was thought to be due to the increased oxygen tension below sea level.

The most widely accepted guideline for prescribing oxygen use during exercise is that of exercise-induced  $SpO_2$  below 90%. However, it seems reasonable to recommend that measurements of dyspnea and exercise tolerance be undertaken with and without supplemental oxygen to determine which individuals are less short of breath or walk further (have greater exercise tolerance) when given supplemental oxygen (145). Certainly, exercise-induced decreases in  $SpO_2$  below 90% when combined with increased exercise tolerance with oxygen therapy warrant the prescription of oxygen therapy during exercise.

Patients with mild-to-moderate daytime hypoxemia often have marked nocturnal desaturation. Home overnight oximetry can be used to diagnose nocturnal oxyhemoglobin desaturation and assist in oxygen prescription although guidelines for sleep supplemental oxygen have not been established (146).

Inspiratory phase or pulsed oxygen therapy, especially when delivered transtracheal, avoids waste and decreases discomfort and drying of mucous membranes. Oxygen flow

delivery is 0.25 to 0.4 L/min compared to 2 to 4 L/min when delivered via nasal cannula or face mask (147,148). Oxygen therapy should be used in combination with mechanical ventilation for patients with concomitant carbon dioxide retention.

### Reconditioning Exercise

COPD patients are markedly inactive during and after hospitalizations for acute exacerbations. Those with low activity levels 1 month postdischarge were significantly more likely to be hospitalized during the next year. Patients who had hospitalizations for exacerbations in the previous year were even more deconditioned than patients with recent hospitalizations. Thus, efforts to enhance physical activity and exercise tolerance are especially important for patients experiencing acute exacerbations (149).

Because of decreased efficiency of gas exchange, there is an abnormally high ventilatory requirement and a rapid increase in breathing frequency by comparison to tidal volume during exercise. The COPD patient's maximal exercise ventilation ( $\dot{V}E_{\max}$ ) is close to or exceeds maximum voluntary ventilation. Cardiac output rises normally with exercise, but exercise can cease at relatively low heart rates because of the ventilatory limitation associated with dyspnea. Hypoxia—and in severely limited patients hypercapnia—may occur with exercise (150). Thus, not all patients can attain the 60% to 70% of predicted maximum heart rate and the minute oxygen consumption needed for cardiac or aerobic exercise training. Even when the ventilatory anaerobic threshold (VAT) cannot be achieved, however, maximum symptom-limited oxygen consumption does correlate with ability to perform ADL, and it can be significantly increased with exercise training (151).

Independent of LTOT, it has been suggested that rehabilitation with exercise reconditioning may prolong survival for COPD patients (152). For 149 patients, 89% of whom had COPD and mean age of 69 years, age, sex, body mass index, and primary diagnosis were not related to survival after completion of a pulmonary rehabilitation program. However, a higher postrehabilitation functional activities score, a longer postrehabilitation 6-min walk distance, and being married were strongly associated with increased survival (153). Gerardi et al. also demonstrated that postrehabilitation 12-min walk was a strong predictor of survival and much better than arterial partial pressure of oxygen ( $\text{PaO}_2$ ), partial pressure of carbon dioxide ( $\text{PaCO}_2$ ),  $\text{FEV}_1$ , and nutritional status (154). Thus, exercise tolerance is extremely important for predicting survival. A recent study suggests the importance of ongoing rehabilitation for COPD patients (155).

In normal male subjects, as well as in COPD patients, the intensity of training is the most important factor in improving maximum oxygen consumption ( $\text{VO}_{2\max}$ ). Greater exercise tolerance results from high-intensity programs. Punzal et al. demonstrated that moderately to severely affected COPD patients could exercise at 95% of the baseline maximum treadmill workload. At training weeks 1, 4, and 8, they can train at 85%, 84%, and 86%, respectively, of initial baseline maximum.

Maximum treadmill workload,  $\text{VO}_{2\max}$ , and endurance exercise time can be increased and symptoms decreased in this manner (156). The minority of patients who did not reach the VAT were able to train at a higher percentage of maximum exercise tolerance than patients who reached VAT, but the increase in exercise performance was similar for both groups. Indeed, moderate to severely affected COPD patients can perform exercise training successfully at intensity levels that represent higher percentages of maximum, than typically recommended in normal individuals or other patients (156). Although both men and women benefit from short-term (3-month) exercise therapy with improvements in dyspnea, fatigue, and emotional function, men, but not women, continued to benefit from long-term exercise therapy (157).

The VAT is defined as the highest rate of oxygen consumption during exercise above which sustained lactic acidosis occurs. The VAT can be consistently achievable for patients with less than very advanced disease, including patients with 0.5 L of  $\text{FEV}_1$ . The parameters of a 45-minute, maximally intense, training prescription can be derived from bilevel exercise in cycles of 4 minutes of exercise at the VAT (lower level) and 1 minute at the  $\text{VO}_{2\max}$  (upper level) (158). For the minority of cases for whom the VAT cannot be achieved, bilevel exercise can be provided by using the maximum  $\text{VO}_2$  attained for the upper (1-minute) level and 40% of this figure for the lower (4-minute) level. These intensities can be maintained for 45 minutes in a maximally intense endurance exercise program using a cycle ergometer, such as a Square Wave Endurance Exercise Trainer (158).

Imprecisely prescribed exercise regimens—for example, when the exercise is too intense to be tolerated for a 45-minute session—will result in patients failing to complete the prescribed sessions and deriving suboptimal benefits on endurance. Others, for whom the prescription is submaximal, will be able to complete the 45-minute sessions but at exercise intensities inadequate for optimal reconditioning. Submaximal exercise programs have not been demonstrated to increase  $\text{VO}_{2\max}$  or reduce lactate production. Increases in  $\text{VO}_{2\max}$  can result in both lower ventilation requirement at given exercise levels and increased exercise tolerance.

Some advocate guiding initial exercise intensity by parameters of clinical exercise testing, for example, heart rate at ventilation levels of 37.5 times the  $\text{FEV}_1$  (24). Such patients can increase exercise ventilation and sustain it at a high percentage of their maximum voluntary ventilation. With training, they can exceed the levels attained during initial exercise testing (106). For example, 34 patients in one study could walk at a work level of 86% of their baseline maximum for a mean duration of 22 minutes (106). Carter et al. also trained patients at near their ventilatory limits and reported mean peak exercise ventilation of 94% to 100% of measured maximum voluntary ventilation (159). Training above the VAT leads to a reduced ventilatory requirement during exercise and, therefore, improved maximum exercise tolerance (159).

Others prescribe maximum sustainable exercise by encouraged 6-minute walking (160). This can be a high-intensity

submaximal exercise protocol in which oxygen uptake plateaus after the third minute. Relatively high levels of oxygen consumption to  $1.6 \pm 0.3$  L/m were achieved in eight subjects with moderate COPD and exercise tolerance increased (161). The pulse should return to baseline 5 to 10 minutes after exercise.

Walking, stair climbing, calisthenics, bicycling, and pool activities may be used for reconditioning. The patient is made responsible for a progressive program. As a minimum, we recommend the purchase of a stationary bicycle for the patient's home and prescribe its daily use. A daily 12-minute walk is recommended, as well as daily 15-minute sessions of inspiratory muscle training. A daily log of time and distance walked, bicycled, and the inspiratory resistance tolerated during the 15-minute sessions, provides feedback to both the patient and the physician. A typical program consists of weekly re-evaluations for 10 to 12 weeks, during which the patient logs are reviewed and exercise parameters modified. Educational and peer groups sessions reinforce the activities. Exercises for skeletal musculature that include bench presses, lateral pull down, leg extension, and presses may improve the 6-minute walk (160). Such programs are inexpensive, minimally intrusive, and optimize the chances for continued independent adherence to the protocol following the 10- to 12-week supervision period.

### Upper Extremity Exercise

Upper extremity reconditioning is part of any comprehensive program (162–167). Many arm and shoulder muscles are also accessory muscles of respiration and, as such, are very active for patients with COPD. The overlap in function explains why COPD patients are particularly short of breath when performing upper extremity ADL.

Unsupported upper extremity activities range from typing, lifting, reaching, and carrying, to athletic activities and personal daily care (eating, grooming, cleaning). Unsupported arm exercise shifts work to the diaphragm, leading to earlier fatigue (164). In a randomized controlled trial comparing supported arm exercise with unsupported arm exercise within a general rehabilitation program for COPD patients, the group performing the unsupported upper extremity exercise demonstrated significantly greater improvements and reduced oxygen consumption during upper extremity exercise than the supported upper extremity exercise group (165). Other studies have substantiated the greater benefits to be derived from unsupported rather than supported upper extremity exercise (164–168).

### Physical Aids

Wheelchairs and other assistive equipment are covered elsewhere in this text (see Chapters 50 and 74). However, certain aids like motorized scooters and Rollators can greatly improve function and quality of life for COPD patients. Rollators (essentially rolling walkers that permit the user to sit) were reported to be effective in improving functional exercise capacity by reducing dyspnea and rest duration among stable individuals with severe

COPD (169,170). Those who walked less than 300 m and those who required a rest during an unaided 6-minute walk benefited the most by reduced dyspnea, reduced rest time, and improved distance walked. Hospital beds with an overhead trapeze, reachers, elevated toilet seats, and strategically placed hand rails at home can also be very useful.

### The Results of Pulmonary Rehabilitation

In a review of 48 pulmonary rehabilitation studies that included exercise reconditioning, exercise tolerance improved significantly in all 48, including 14 controlled studies (29). It improved significantly (proportionally) in patients with mild or advanced (hypercapnic) disease (171). Consistent improvements included decreases in the ventilatory equivalent or the ventilation/oxygen consumption ratio, increases in work efficiency (external work per unit of oxygen consumed) and thus in exercise tolerance, ambulation capacity, general well-being, and dyspnea tolerance. The patients developed better performance strategies and greater confidence in performing the tests. In many programs, decreases in blood lactate levels were also observed in combination with higher  $\text{VO}_{2\text{max}}$ , implying a physiologic training effect as well as improved motivation and effort. Maximum tolerated intensity exercise regimens yielded better results than low-intensity exercise for proportionally longer periods (158,172,173). Twenty session out-patient programs result in better outcomes than ten session programs (174), and minimally supervised home exercise programs can also result in improved health status (175).

In general, peak performance appeared to be reached in 26 to 51 weeks and lasted for as long as 5 years (172,173,176–178). Quality-of-life measures (29,179–181), hospitalization rates, postoperative pulmonary complications (182), and physical functioning were likewise reported to be significantly improved in the majority of both the controlled and the repetitive measure studies (29). Outcomes were equivalent for inpatient and outpatient programs, although many of the outpatient programs were predominantly home based. Pulmonary function parameters, such as  $\text{FEV}_1$ , did not significantly improve in 31 of 35 studies (29).

Thus, virtually all studies indicate that pulmonary rehabilitation including exercise training results in significant increases in ambulation capacity and exercise endurance for COPD patients, as well as for many patients with other intrinsic lung pathology (183). The often-reported decreased resting oxygen consumption and carbon dioxide production may, at least in part, account for the significant decrease in perception of dyspnea, the general increase in functional performance, and in the often-found improved sense of well-being. Indeed, a recent Cochrane meta-analysis of pulmonary rehabilitation in COPD (184) concluded that “Rehabilitation relieves dyspnea and fatigue, improves emotional function, and enhances patients’ control over their condition. These improvements are moderately large and clinically significant. Rehabilitation forms an important component of the management of COPD.”

One study of 120 advanced hypercapnic COPD patients, 117 of whom with  $\text{FEV}_1$  less than 1 L, demonstrated significant

increases in  $\text{PaO}_2$ , vital capacity (VC),  $\text{FEV}_1$ , maximum inspiratory pressures, and ambulation tolerance with pulmonary rehabilitation, including exercise reconditioning. Maximum expiratory pressures did not change significantly. The higher the initial  $\text{PaCO}_2$ , the more  $\text{PaCO}_2$  fell and  $\text{PaO}_2$  rose during the rehabilitation program. The patients' improvement in performance of ADL correlated with increased walking distance. Thus, hypercapnia is not a contraindication to intensive rehabilitation, and the use of rigorous reconditioning exercise does not precipitate respiratory muscle fatigue in this population (171).

In a study of 61 of 80 bedridden ventilator-dependent COPD patients in a respiratory care unit, 60 underwent a stepwise rehabilitation program consisting of skeletal and respiratory muscle training and early ambulation. Twenty percent of both the rehabilitation and nonrehabilitation patients died while in the unit. However, all but nine of the rehabilitation patients were weaned from invasive mechanical ventilation after a mean stay of  $38 \pm 14$  days (34). Six-minute walk distances and mean inspiratory pressure increased significantly more in the rehabilitation group.

Following the acute rehabilitation period, continued surveillance and attention to abstinence from smoking, bronchial hygiene, breathing retraining, physical reconditioning, oxygen therapy, and airway secretion mobilization have been shown to reduce hospital admissions, the length of hospital stays, and cost (185). As noted, the benefits of pulmonary rehabilitation on exercise performance and quality of life persisted for up to 5 years (172,173,176,177,186–189). Pulmonary function parameters, dyspnea, exercise tolerance, and quality of life are not further improved long term by yearly repeated 2-month outpatient pulmonary rehabilitation interventions, but rates of hospitalizations and acute exacerbations are further decreased by repeated interventions (190). The principles of rehabilitation for COPD are being increasingly applied to patients with asthma with similar outcomes (191).

## PHYSICAL MEDICINE AND HABILITATION OF PATIENTS WITH PARALYTIC AND NEUROMUSCULAR IMPAIRMENTS

Physiatrists have been instrumental in developing the habilitation techniques, orthotics, and assistive equipment that have been used to optimize quality of life for patients with neuromuscular disability (192). Since the early 1950s, they have also reported most of the physical medicine aids that have been used to prevent respiratory failure for patients with dysfunctional respiratory muscles (193). Despite this history, few physiatrists today are aware of these methods.

### Pathophysiology

Ventilatory insufficiency is defined by hypercapnia in the presence of a normal arterial-alveolar A-a gradient. It is hypercapnia not caused by intrinsic lung disease, or irreversible upper

or lower airway obstruction, as in COPD. These patients can have airway obstruction from bronchial mucous plugging that causes an elevated A-a gradient. However, the mucous plugging is reversible by using expiratory (cough) aids. Symptomatic hypercapnic patients benefit from the use of noninvasive ventilation for at least part of the day and, more often overnight. With progressive inspiratory muscle weakness, ventilator-free breathing ability is eventually lost.

Ventilatory muscle failure is defined by the inability of the inspiratory and expiratory muscles to sustain one's respiration without resorting to ventilator use. Ventilatory insufficiency leading to failure can be nocturnal only resulting from diaphragm dysfunction with the patient unable to breathe when supine, or can result from a lack of central ventilatory drive, or can result from severe generalized respiratory muscle dysfunction. Many patients with ventilatory insufficiency survive for years without ventilator use with the cost of orthopnea and increasing hypercapnia, associated symptoms and dangers, and a compensatory metabolic alkalosis that depresses central ventilatory drive. The alkalosis allows the brain to accommodate to hypercapnia without overt symptoms of acute ventilatory failure. Hypercapnic patients not using NIV, and especially those receiving supplemental oxygen, develop increasingly severe hypercapnia that eventually results in coma from carbon dioxide narcosis and ventilatory arrest. When symptomatic, hypercapnic patients are treated with NIV, blood gases normalize, and the alkalosis resolves as the kidneys excrete excess bicarbonate ions. Because of the need to take bigger breaths to maintain normal  $\text{PaCO}_2$  and blood pH levels, a nocturnal-only ventilator user can become dyspneic when discontinuing ventilator use in the morning and require gradually increasing periods of daytime NIV and eventually become continuously NIV dependent. Such patients eventually require NIV for increasing periods during the day until continuously NIV dependent. Some patients with ventilatory muscle failure and no measurable VC with their respiratory muscles use only nocturnal aid and rely on glossopharyngeal breathing (GPB) to ventilate their lungs during daytime hours.

For patients with primarily ventilatory impairment, respiratory morbidity and mortality are a direct result of respiratory muscle dysfunction and can be avoided by assisting respiratory muscles, as long as bulbar muscle dysfunction is not so severe that the  $\text{SpO}_2$  remains below 95% because of continuous aspiration of saliva. Such patients develop essentially irreversible upper airway obstruction and require tracheostomy tubes to protect the airway. In general, this scenario occurs for bulbar amyotrophic lateral sclerosis (ALS) patients who have lost the ability to speak and for few other patients with NMD.

### Epidemiology

There are 500,000 people in the United States, or 0.15% of the population, with pediatric NMD (194), and many more with thoracic wall restrictive lung disease. One out of 3,500 boys is born with DMD, one in 5,000 children have spinal muscular atrophy (SMA), and 1 in 1,800 people develop ALS. It has been estimated that of the patients who had acute

**TABLE 42.3** Conditions with Chronic Alveolar Hypoventilation Manageable with Respiratory Muscle Aids

Myopathies: Congenital, metabolic, inflammatory, and mitochondrial myopathies, myopathies of systemic disease such as carcinomatous myopathy, cachexia/anorexia nervosa, medication and ICU-associated, muscular dystrophies such as Duchenne and Becker, limb girdle, Emery-Dreifuss, facioscapulohumeral, congenital, and myotonic
Endocrine related as with hypothyroidism, acromegaly
Mixed connective tissue disease and arthrogryposis
Anterior horn cell disorders: Spinal muscular atrophies, motor neuron diseases, poliomyelitis
Neuropathies: Hereditary sensory motor neuropathies
Familial hypertrophic interstitial polyneuropathy
Phrenic neuropathies
Guillain-Barré syndrome
CNS disorders: Multiple sclerosis
Disorders of supraspinal tone such as Friedreich's ataxia
Central hypoventilation syndromes, hypoventilation associated with diabetic microangiopathy, familial dysautonomia, Prader-Willi syndrome
Encephalopathies: Syringomyelia, myelomeningocele
Myelopathies: Traumatic and spondylitic medical including rheumatoid, infectious, vascular, botulism/pancuronium bromide, or idiopathic
Restrictive lung disease/increased work of breathing:
Obesity-hypoventilation, Kyphoscoliosis
Lung resection/tuberculosis, Milroy's disease, congenital diaphragmatic hernia, vocal cord paralysis/postlaryngotracheal reconstruction
Mixed ventilatory-respiratory impairment like COPD, CF

poliomyelitis, 1.63 million with a median age of 57 were still alive in 1987 (194). Many of these patients have ventilatory insufficiency and require ventilator use currently. Respiratory muscle dysfunction amenable to treatment by respiratory muscle aids occurs in many people with the diagnoses listed in Table 42-3.

Surveys in the United States, Western Europe, and Japan indicate that the use of home mechanical ventilation is increasing rapidly (194). Most people who appear to require more than nocturnal ventilator use, however, and those who have difficulty weaning when intubated during chest infections generally undergo tracheotomy. This usually occurs because of lack of awareness of how to introduce physical medicine aids. Likewise, 90% of episodes of ARF for young patients with NMD occur as a result of inability to generate effective cough peak flows (CPF) during otherwise benign upper respiratory infections (195). These episodes are usually avoidable (196).

### What Are Physical Medicine Respiratory Muscle Aids?

Inspiratory and expiratory muscle aids are devices and techniques that involve the manual or mechanical application of forces to the body, or intermittent pressure changes to the airway, to assist inspiratory or expiratory muscle function. The devices that act on the body include body ventilators that create pressure changes around the thorax and abdomen. Negative pressure applied to the airway during expiration assists coughing, just as positive pressure applied to the airway during inhalation (NIV) assists the inspiratory muscles. Continuous positive airway pressure (CPAP) does not assist ventilation and is not useful for patients with primarily ventilatory impairment.

### Patient Evaluation

Patients with diminished ventilatory reserve who are able to walk commonly complain of exertional dyspnea. Eventually, morning headaches, fatigue, sleep disturbances, and hypersomnolence develop (197). For wheelchair users, symptoms may be minimal, except during intercurrent respiratory infections when anxiety, inability to fall asleep, and dyspnea become problems.

The patient is observed for increased respiratory rate, decreased depth, or irregularity of breathing. Paradoxical breathing, or asymmetric movement of the abdomen or thorax is often present. Hypophonia, nasal alae flaring, use of auxiliary respiratory musculature, peribuccale or generalized cyanosis, flushing or pallor, hypertension, difficulty controlling airway secretions, dysphagia, regurgitation of fluids through the nose, nasality of speech, cor pulmonale, confusion, and fluid retention may all be signs of ventilatory insufficiency.

Maximum inspiratory and expiratory pressures generated at the mouth correlate best with inspiratory and expiratory muscle strength. Maximum voluntary ventilation gauges respiratory muscle endurance. The VC gives an indication of both these parameters and is simple, easy to measure, objective, and very reproducible. Because hypoventilation is often worse during sleep, the supine rather than sitting position VC is the most important indicator of ventilatory dysfunction. Spirometry is also useful for monitoring progress with GPB and air stacking. A patient's maximum insufflation capacity (MIC) is determined by giving the patient the largest volume of air that can be held with a closed glottis from a manual resuscitator or a portable ventilator that is volume cycled. The patient then expels the air into the spirometer. Patients who learn GPB can often air stack consecutive GPB gulps to or beyond the MIC (198). A nasal interface or lip seal can be

**FIGURE 42-2.** Fifteen-year-old patient with acute high-level spinal cord injury, continuously ventilator dependent from 12 h postinjury. Never intubated, he uses lip seal intermittent positive pressure ventilation (IPPV) while sleeping (seen here) and a simple mouth piece for IPPV while awake, without ventilator-free breathing ability, for 10 days before weaning from ventilator use. Because there is no neck movement, the lip seal is used with a single Velcro strap to the posterior poster rather than the customary two straps.

used for air stacking when the lips are too weak for effective air stacking via the mouth (Fig. 42-2).

Unassisted and assisted CPF are measured using a peak flow meter (Access Peak Flow Meter, Healthscan Products Inc., Cedar Grove, NJ). CPF of 160 L/m are the minimum needed to cough effectively (199), and this is the best indicator for tracheostomy tube removal irrespective of remaining pulmonary function (200) (Fig. 42-3). Indeed, almost 40% of patients with ALS can survive despite continuous ventilator dependence using strictly noninvasive aids (201). Patients with VCs less than 1,500 mL have assisted CPF measured from a maximally stacked volume of air and with an abdominal thrust delivered simultaneously with glottic opening.

**FIGURE 42-3.** Cough peak flows increase from ineffective levels (below 160 L/m) to effective levels by maximally insufflating the patient and then providing an abdominal thrust. (With permission and appreciation to Dr. Yuka Ishikawa, Dept. of Pediatrics Yakumo Byoin National Sanatorium, Yakumo-cho Hikaricho.)

For the stable patient without intrinsic pulmonary disease, arterial blood gas sampling is unnecessary. Besides the discomfort, 25% of patients hyperventilate as a result of anxiety or pain during the procedure (99). Noninvasive continuous blood gas monitoring, including capnography and oximetry, yield more useful information, particularly during sleep.

Nocturnal noninvasive blood gas monitoring can be performed for patients with diminished supine VC, especially for those with rapidly evolving conditions and symptoms suggestive of hypoventilation. The oximeter and the capnograph, which measures end-tidal  $p\text{CO}_2$ , must be capable of summarizing and printing out the data (197). These studies are most conveniently performed in the home. When symptoms are obvious, a trial of nocturnal NIV rather than nocturnal end-tidal  $\text{CO}_2$  and oximetry monitoring is more appropriate. Any symptomatic patient with decreased VC, multiple nocturnal oxyhemoglobin desaturations below 95%, and elevated nocturnal  $\text{PaCO}_2$  certainly requires treatment for nocturnal hypoventilation.

For symptomatic patients with normal VC, an unclear pattern of oxyhemoglobin desaturation, and no apparent carbon dioxide retention, sleep disordered breathing is suspected. This is particularly true when loud high-pitched snoring, interrupted breathing, and hypersomnolence dominate the picture (202). These patients undergo polysomnography and are considered for CPAP therapy. Obesity-hypoventilation patients are treated with nocturnal ventilatory support, as are NMD patients. When concurrent COPD or interstitial lung disease is documented, capnography is correlated to  $\text{PaCO}_2$ .

### The Intervention Objectives

The intervention goals are to maintain lung and chest-wall compliance and to promote normal lung and chest-wall growth for children, to maintain normal alveolar ventilation

around the clock, and to maximize CPF. The long-term goals are to avert episodes of ARF during intercurrent chest infections, avoid hospitalizations, and prolong survival without resorting to tracheotomy. All goals can be attained by evaluating, training, and equipping patients in the outpatient setting and at home.

### **Goal One: Maintain Pulmonary Compliance, Lung Growth, and Chest-Wall Mobility**

Pulmonary compliance is lost because the ability to expand the lungs to the predicted inspiratory capacity is lost as the VC decreases. As the VC decreases, the largest breath that one can take can only expand a small portion of the lungs. Like limb articulations and other soft tissues, regular range of motion (ROM) is required to prevent chest-wall contractures and lung restriction. This can only be achieved by providing deep insufflations, air stacking, or nocturnal NIV (203). The extent to which the MIC is greater than the VC predicts the capacity of the patient to be maintained by noninvasive rather than tracheostomy ventilatory support (199). This is because the MIC, VC difference, like assisted CPF, is a function of bulbar muscle integrity. Patients who cannot close the glottis and, therefore, cannot air stack, must be passively insufflated using a CoughAssist (Respironics International Inc., Murrysville, PA) or pressure-cycling ventilator at pressures of 40 to 70 cm H<sub>2</sub>O. The maximum passive insufflation volume can be termed the “Lung Insufflation Capacity” or LIC (204).

The primary objectives in using air stacking or maximum insufflations for lung and chest-wall ROM are to increase the VC and MIC, to maximize CPF (see Fig. 42-3), to maintain or improve pulmonary compliance, to prevent or eliminate atelectasis, and to master NIV. In 282 spirometry evaluations of NMD patients for VC, MIC, and LIC, the authors found mean values of  $1131 \pm 744$  mL,  $1712 \pm 926$  mL, and  $2069 \pm 867$  mL, respectively (204). With the higher lung volumes by air stacking, assisted CPF were  $4.3 \pm 1.7$  L/s by comparison with  $2.5 \pm 2.0$  L/s unassisted. The deeper lung volumes by air stacking also permitted patients to raise voice volume as desired.

Because any patient who can air stack is also able to use NIV, if such a patient is intubated for respiratory failure, he or she can be extubated directly to continuous NIV regardless of whether the patient regained any breathing tolerance (205). Extubation of a patient with little or no breathing tolerance who has not been trained in NIV can result in panic, ventilator dyssynchrony, asphyxia, and possible need for reintubation.

Before patients' VCs decrease to 70% of predicted normal, they are instructed to air stack 10 to 15 times at least two or three times daily. Thus, the first respiratory equipment that is prescribed for patients with ventilatory impairment is often a manual resuscitator. In general, because of the importance of air stacking, NIV is provided via portable ventilators on assist/control mode rather than by pressure-limiting devices.

Infants cannot air stack or cooperate to receive maximal insufflations. All babies with SMA type 1, infants with SMA

type 2, and others with infantile NMD who have paradoxical chest-wall movement require nocturnal NIV to prevent pectus excavatum and promote lung growth as well as for ventilatory assistance (206). In addition to nocturnal aid, deep insufflations can be provided via oral-nasal interface and manual resuscitator by timing the delivery of air to the child's breathing phases. Children can become cooperative with deep insufflation therapy by 14 to 30 months of age.

### **Goal Two: Continuously Maintain Normal Alveolar Ventilation by Assisting Inspiratory Muscles as Needed**

#### **I. The Nocturnal Inspiratory Muscle Aids**

##### **A. Negative pressure body ventilators**

The NPBVs available today include the iron lung, the Porta-Lung, chest-shell ventilator, and various wrap-style ventilators. They are only practical for use during sleep. Although NPBVs have been used by patients with little or no VC for decades, they become ineffective with aging and decreasing pulmonary compliance (117). Such patients are switched to noninvasive IPPV (207,208). Although NPBVs continue to be used in a few centers as a “bridge” to noninvasive IPPV while extubating unweanable patients (209), it is debatable whether their long-term use is ever warranted today due to the positive pressure devices available.

##### **B. Noninvasive intermittent positive pressure ventilation**

Although for acutely ill patients, introduction of noninvasive ventilation needs to be done in the hospital setting, the great majority of noninvasive IPPV users are introduced to it in the clinic or home setting.

IPPV can be noninvasively delivered via mouthpieces, nasal, and oral-nasal interfaces for nocturnal ventilatory support. Mouthpiece and nasal IPPV are open systems that require the user to rely on central nervous system reflexes to prevent excessive insufflation leakage during sleep (197,210).

There are numerous commercially available nasal interfaces (CPAP masks). Each interface design applies pressure differently to the paranasal area. One cannot predict which model will be most effective and preferred by any particular patient. Nasal bridge pressure and insufflation leakage into the eyes are common symptoms with several of these generic models. Such difficulties can be avoided by using nasal prong systems or custom designs (6,197,211). No patient should be offered and expected to use only one nasal interface. Alternating IPPV interfaces nightly alternates skin pressure sites, minimizes discomfort, and is to be encouraged.

Excessive insufflation leakage can be avoided by switching to the use of lip seal–nasal prong systems that provide an essentially closed system of noninvasive ventilatory support. Such interfaces deliver air via mouth and nose during sleep with minimal strap pressure. This optimizes skin comfort and minimizes air (insufflation) leakage. Excessive leakage can also be prevented

**FIGURE 42-4.** A postpolio survivor with no measurable VC since 1952 using an IAPV (Exsufflation Belt, Respironics International Inc., Murrysville, PA) during daytime hours and lip seal IPPV nightly since 1956. The air bladder inside the girdle is connected to the ventilator circuit (seen here), then the girdle is placed under the clothes and over the patient's abdomen.

by sustaining ventilatory drive by maintaining normal daytime  $\text{CO}_2$  and avoiding supplemental  $\text{O}_2$  and sedatives.

## II. The daytime inspiratory muscle aids

### C. Body ventilators

The intermittent abdominal pressure ventilator (IAPV) involves the intermittent inflation of an elastic air sac that is contained in a corset or belt worn beneath the patient's outer clothing (Fig. 42-4) (Exsufflation Belt, Respironics Inc., Murrysville, PA). The sac is cyclically inflated by a positive pressure ventilator. Bladder inflation moves the diaphragm upward to assist in expiration. During bladder deflation, gravity causes the abdominal contents and diaphragm to return to the resting position, and inspiration occurs passively. A trunk angle of 30 degrees or more from the horizontal is necessary for it to be effective. If the patient has any inspiratory capacity or is capable of GPB, he or she can add volumes of air autonomously taken in to that taken in mechanically. The IAPV generally augments tidal volumes by about 300 mL, but volumes as high as 1,200 mL have

been reported (212). Patients with less than 1 hour of breathing tolerance usually prefer to use the IAPV rather than use noninvasive IPPV during daytime hours.

### D. Mouthpiece intermittent positive pressure ventilation

Mouthpiece IPPV is the most important method of daytime ventilatory support. Some patients keep the 15-mm angled mouthpiece between their teeth all day. Most patients prefer to have the mouthpiece held near the mouth. A metal clamp attached to a wheelchair can be used for this purpose, or the mouthpiece can be fixed onto motorized wheelchair controls—most often, sip and puff, chin, or tongue controls (Fig. 42-5). The ventilator is set for large tidal volumes, often 1,000 to 2,000 mL. The patient grabs the mouthpiece with his mouth and supplements or substitutes for inadequate autonomous breath volumes. The patient varies the volume of air taken from ventilator cycle to ventilator cycle and breath to breath to vary speech volume and cough flows as well as to air stack to fully expand the lungs.

To use mouthpiece IPPV effectively and conveniently, adequate neck rotation and oral motor function

**FIGURE 42-5.** Forty-one-year-old man with Duchenne muscular dystrophy who has used 24-h mouthpiece IPPV for 29 years, now with less than 1 minute of breathing tolerance. The mouthpiece is fixed adjacent to the chin/tongue controls of his motorized wheelchair.

are necessary to grab the mouthpiece and receive IPPV without insufflation leakage. To prevent the latter, the soft palate must move posterior and caudally to seal off the nasopharynx. In addition, the patient must open the glottis and vocal cords, dilate the hypopharynx, and maintain airway patency to receive the air. These normally reflex movements may require a few minutes to relearn for patients who have been receiving IPPV via invasive tubes.

#### E. Nasal intermittent positive pressure ventilation

Because patients prefer to use mouthpiece IPPV or the IAPV for daytime use (163,183), nasal IPPV is most practical for nocturnal use. Daytime nasal IPPV is indicated for infants and for those who cannot grab or retain a mouthpiece because of oral muscle weakness, inadequate jaw opening, or insufficient neck movement. Nevertheless, 24-hour nasal IPPV can be a viable and desirable alternative to tracheostomy, even for some patients with severe lip and oropharyngeal muscle weakness (197). Nasal IPPV users learn to close their mouths or seal off the oropharynx with their soft palates and tongues to prevent oral insufflation leakage.

### Complications of Noninvasive Intermittent Positive Pressure Ventilation

Besides orthodontic deformities and skin pressure from the interface, other potential complications include very infrequent allergy to the interface, dry mouth (65%), eye irritation from air leakage, nasal congestion (25%) and dripping (35%),

**TABLE 42.4** Relative Contraindications for Long-Term Noninvasive Intermittent Positive Pressure Ventilation (IPPV)

1. Lack of cooperation or use of heavy sedation or narcotics
2. Need for high levels of supplemental oxygen therapy
3. Oxyhemoglobin saturation ( $SpO_2$ ) cannot be maintained above 94% despite noninvasive IPPV and optimal use of assisted coughing techniques when needed
4. Substance abuse or uncontrollable seizures
5. Bulbar-innervated muscle impairment with inability to close the glottis
6. Conditions that interfere with the use of IPPV interfaces, i.e., facial fractures, inadequate bite for mouthpiece entry, presence of facial hair that hamper airtight interface seal
7. Inadequate caregiver support

sinusitis (8%), nose bleeding (4% to 19%), gum discomfort and receding from nasal interface or bite-plate pressure (20%), maxillary flattening in children, aerophagia (213), and, as for invasive ventilation, barotrauma. In addition, occasional patients experience claustrophobia. Proper interface selection eliminates or minimizes these difficulties.

Pressure drop-off through the narrow air passages of the nose is normally between 2 and 3 cm  $H_2O$ . Suboptimal humidification dries out and irritates nasal mucous membranes, causes sore throat, and results in vasodilatation and nasal congestion. Increased airflow resistance to 8-cm  $H_2O$  can be caused by the loss of humidity that is due to unidirectional airflow with expiration via the mouth during nasal CPAP or IPPV (214). This problem cannot be ameliorated by using a cold pass-over humidifier, but the increase in airway resistance can be reduced by 50% by warming the inspired air to body temperature and humidifying it with the use of a hot-water bath humidifier (214). Decongestants can also relieve sinus irritation and nasal congestion. Switching to lip seal-only interface can relieve most if not all difficulties associated with nasal IPPV. There are no absolute contraindications to the long-term use of noninvasive inspiratory muscle aids (215). Relative contraindications are listed in Table 42-4.

Abdominal distention tends to occur sporadically in non-invasive IPPV users. The air usually passes as flatus once the patient gets up or is placed into a wheelchair in the morning. When severe, it can present as intestinal pseudo-obstruction with diminished bowel sounds and increased ventilator dependence. A rectal tube can usually decompress the colon; a gastrostomy tube, when present, can be burped; or a nasogastric tube can be passed to relieve the problem.

Barotrauma results from rupture of the boundary between the alveoli and the bronchovascular sheath. Although its incidence has been cited as 4% to 15% for intensive care unit invasive ventilation users with primarily respiratory impairment (216), in 139 patients it has been reported to occur in 60% of those with acute respiratory distress syndrome but was absent for those with congestive heart failure or neurologic

disease (217). We have had one case of pneumothorax in over 1000 NIV users.

Inspissated secretions can be life threatening (218,219). Secretion encumbrance for patients with primarily ventilatory impairment results from failure to use assisted coughing. Chronic aspiration of saliva to the extent of lowering baseline  $\text{SpO}_2$  can overwhelm normally sterile airways and lead to pneumonia (220), tracheitis, bronchitis (221), and chronic lung disease (220). The indication for tracheostomy is  $\text{SpO}_2$  baseline less than 95% as a result of chronic airway secretion aspiration. This is rare other than for a verbal, severe bulbar impaired ALS patients.

### Goal Three: Provide Functional Coughs by Assisting Expiratory Muscles

#### I. Why are expiratory muscle aids needed?

Bulbar, inspiratory, and expiratory muscles are needed for effective coughing. The latter are predominantly the abdominal and intercostal muscles. Clearing airway secretions and airway mucus can be a continual problem for patients who cannot swallow saliva or food without aspiration. For patients with respiratory muscle dysfunction and functional bulbar musculature, it becomes a problem during chest infections, following general anesthesia, and during any other periods of bronchial hypersecretion.

#### II. Manually assisted coughing

Assisted CPF can be greatly increased in patients receiving maximal insufflations followed by manual thrusts for assisted coughing (222). In 364 evaluations of our NMD patients able to air stack, the mean VC in the sitting position was 996.9 mL, the mean MIC was 1647.6 mL, and although CPFs were 2.3 L/s (<2.7 L/s or the minimum needed to eliminate airway secretions) mean assisted CPF were 3.9 L/s.

Techniques of manually assisted coughing involve different hand and arm placements for expiratory cycle

thrusts (Fig. 42-6). An epigastric thrust with one hand, while applying counterpressure across the chest to avoid paradoxical chest expansion with the other arm, further increases assisted CPF for 20% of patients (223). Manually assisted coughing is usually ineffective in the presence of severe scoliosis because of a combination of restricted lung capacity and the inability to effect diaphragm movement by abdominal thrusting because of severe rib-cage and diaphragm deformity. Abdominal compressions should not be used for 1 to 1.5 hours following a meal. When inadequate, and especially when inadequacy is due to difficulty air stacking, the most effective alternative for generating optimal CPF and clearing airway secretions is the use of mechanical insufflation-exsufflation (MI-E).

The inability to generate more than 2.7 L/s or 160 L/m of assisted CPF despite having a VC or MIC greater than 1 L usually indicates fixed upper-airway obstruction or severe bulbar muscle weakness and hypopharyngeal collapse during coughing attempts. Vocal cord adhesions or paralysis may have resulted from a previous translaryngeal intubation or tracheostomy (224). Because some lesions, especially the presence of obstructing granulation tissue, can be corrected surgically, laryngoscopic examination is warranted especially before decanulation.

#### III. Mechanical insufflation-exsufflation

##### A. Introduction of MI-E

MI-Es (Cough Assist TM, Respironics International Inc., Murrysville, Pa) deliver deep insufflations followed immediately by deep exsufflations. The insufflation and exsufflation pressures and delivery times are independently adjustable. Insufflation to exsufflation pressures of +40 to -40 cm  $\text{H}_2\text{O}$  are usually the most effective and preferred by most patients. Onset of insufflation generates an insufflation flow peak and a lung insufflation of more than 2 L. Mechanical exsufflation generates two exsufflation flow notches.

A

B

**FIGURE 42-6.** Hand placement for manually assisted coughing.

One occurs when the insufflation pressure stops and is due to the elastic recoil of the lung. The second one, a bit greater, is caused by the exsufflation pressure itself. Except after a meal, an abdominal thrust is applied in conjunction with the exsufflation (MAC, or mechanically assisted coughing). MI-E can be provided via an oral-nasal mask, a simple mouthpiece, or via a translaryngeal or tracheostomy tube. When delivered via the latter, the cuff, when present, should be inflated. The Cough Assist can be manually or automatically cycled. Manual cycling facilitates caregiver-patient coordination of inspiration and expiration with insufflation and exsufflation, but it requires hands to deliver an abdominal thrust, to hold the mask on the patient, and to cycle the machine.

One treatment consists of about five cycles of MI-E or MAC followed by a short period of normal breathing or ventilator use to avoid hyperventilation. Insufflation and exsufflation pressures are almost always from +35 to +60 cm H<sub>2</sub>O to -35 to -60 cm H<sub>2</sub>O. Most patients use 35 to 45 cm H<sub>2</sub>O pressures for insufflations and exsufflations. In experimental models, +40 to -40 cm H<sub>2</sub>O pressures have been shown to provide maximum forced deflation VCs and flows (225). Insufflation and exsufflation times are adjusted to provide maximum chest expansion and rapid lung emptying. In general, 2 to 4 seconds are required. Multiple treatments are given in one sitting until no further secretions are expelled and any secretion or mucus-induced oxyhemoglobin desaturations are reversed. Use can be required as frequently as every 30 minutes around the clock during chest infections.

The use of MI-E via the upper airway can be effective for children as young as 11 months of age. Patients this young can become accustomed to MI-E and permit its effective use by not crying or closing their glottises. Between 2.5 and 5 years of age, most children become able to cooperate and cough on cue with MI-E. Exsufflation-timed abdominal thrusts are also used for infants.

Whether via the upper airway or via indwelling airway tubes, routine airway suctioning misses the left main stem bronchus about 90% of the time (226). MI-E, on the other hand, provides the same exsufflation flows in both left and right airways without the discomfort or airway trauma of tracheal suctioning. Patients prefer MI-E to suctioning for comfort and effectiveness, and they find it less tiring (227). Deep suctioning, whether via airway tube or via the upper airway, can be discontinued for most patients.

#### B. Efficacy of MI-E

The efficacy of MI-E has been demonstrated both clinically and on animal models (228). Flow generation is adequate in both proximal and distal airways to eliminate respiratory tract debris (229,230). VC, pulmonary flow rates, and SpO<sub>2</sub> when abnormal

improve immediately with clearing of airway secretions and mucus by MI-E (231,232). An increase in VC of 15% to 42% was noted immediately following treatment in 67 patients with “obstructive dyspnea,” and a 55% increase in VC was noted following MI-E in patients with neuromuscular conditions (233). We have observed 15% to 400% (200 to 800 mL) improvements in VC and normalization of SpO<sub>2</sub> as MI-E eliminates airway mucus for ventilator-assisted NMD patients with chest infections (223).

#### C. Indications for MI-E

Of the three muscle groups required for effective coughing, MI-E can only take the place of the inspiratory and expiratory muscles. Thus, it cannot be used to avert tracheotomy very long if bulbar function is inadequate to prevent airway collapse, as is often the case in advanced bulbar ALS. On the other hand, patients with completely intact bulbar muscle function, such as most ventilator users with traumatic tetraplegia, can usually air stack to volumes of 3 L or more, and, unless very scoliotic or obese, a properly delivered abdominal thrust can often result in assisted CPF of 6 to 9 L/s. These flows should be more than adequate to clear the airways and prevent pneumonia and respiratory failure without need for MI-E. Thus, the patients who need MI-E the most are those whose bulbar muscle function can maintain adequate airway patency but is insufficient to permit optimal air stacking for assisted CPF more than 250 to 300 L/m. This is typical of most nonbulbar ALS/NMD patients. The most typical example of patients who can consistently avoid hospitalization and respiratory failure by using MI-E during intercurrent chest infections is DMD patients (232). Patients with respiratory muscle weakness complicated by scoliosis and inability to capture the asymmetric diaphragm by abdominal thrusting also greatly benefit from MI-E.

### Glossopharyngeal Breathing

Both inspiratory and, indirectly, expiratory muscle function can be assisted by GPB (198). GPB can provide an individual with weak inspiratory muscles and no VC or breathing tolerance with normal alveolar ventilation when not using a ventilator or in the event of sudden ventilator failure day or night (198,234). The technique involves the use of the glottis to add to an inspiratory effort by projecting (gulping) boluses of air into the lungs. The glottis closes with each “gulp.” One breath usually consists of 6 to 9 gulps of 40 to 200 mL each (Fig. 42-7). During the training period, the efficiency of GPB can be monitored by spirometrically measuring the milliliters of air per gulp, gulps per breath, and breaths per minute. A training manual (235), and numerous videos are available (236), the best of which was produced in 1999 (237).

Although severe oropharyngeal muscle weakness can limit the usefulness of GPB, we have managed 13 DMD ventilator users who had no breathing tolerance other than by

**FIGURE 42-7.** Normal minute ventilation (60 to 90 mL per gulp, 6 to 8 gulps per breath, 12 breaths per minute) throughout daytime hours by GPB for an individual with no measurable VC otherwise. Maximum glossopharyngeal single breath capacities can exceed 3,000 mL for such individuals.

GPB (238). Approximately 60% of ventilator users with no autonomous ability to breathe and good bulbar muscle function can use GPB and discontinue ventilator use for minutes to up to all day (234,239). GPB is also rarely useful in the presence of an indwelling tracheostomy tube. It cannot be used when the tube is uncapped as it is during tracheostomy IPPV, and even when capped, the gulped air tends to leak around the outer walls of the tube and out the stoma as airway volumes and pressures increase during the GPB air-stacking process. The safety and versatility afforded by GPB are additional reasons to eliminate tracheostomy in favor of noninvasive aids.

Because of their generally intact bulbar musculature, spinal cord injury (SCI) patients are ideal candidates to master GPB. High-level SCI patients typically use it for ventilator-free breathing. In some centers, these patients are decannulated to free them from the fear of ventilator failure or accidental ventilator disconnection (234,239). Some patients with no measurable VC have awoken at night, breathing glossopharyngeally, to find that their ventilators had failed, a scenario not possible for tracheostomy IPPV users. When combined with nocturnal noninvasive IPPV, SCI patients can be decannulated, permitting mastery of GPB (Table 42-5) and the security and benefits that accompany decannulation.

### Maintenance of Respiratory Muscle Strength and Endurance

In the few studies of respiratory muscle exercise performed on NMD patients, short daily sessions of inspiratory resistive exercise alone were reported to have no effect on spirometry or maximum inspiratory or expiratory pressures (240,241) but did improve respiratory muscle endurance (240,242). However, the degree of improvement in endurance correlated significantly with the level of VC and maximum inspiratory pressure at the outset of training, and no patient with less than 30% of predicted VC improved (242). This is the level of VC at which point patients often require nocturnal ventilatory

aid and have considerable difficulty during respiratory tract infections (243). There is also no evidence that beginning an exercise program earlier would preserve more muscle function for the time when the patient requires aid, or that the improvement in endurance for relatively strong patients (mean VC: 54% to 59% in the patients studied) delays the occurrence of pulmonary complications as suggested (240). Indeed, there is some evidence to the contrary. Mildly affected ALS patients were reported to respond to a respiratory muscle-resistive exercise program with a decrease in VC and inspiratory pressures (242). There may also be a greater subsequent rate of loss of muscle strength in any temporarily strengthened muscles. The training itself may be hazardous for advanced patients. Thus, for those most likely to have respiratory complications, the use of resistance exercise is likely to be of little or no value.

**TABLE 42.5** Management of Patients with Spinal Cord Injury

Level <sup>a</sup>	VC, mL	Neck/bulbar muscles <sup>b</sup>	Daytime	Nocturnal
Above C1	0	Inadequate/inadequate	TIPPV	TIPPV
C2-C3	<200	Adequate/inadequate	EPR <sub>1</sub>	N/MIPPV
Below C2	>200	Adequate/adequate	MIPPV/IAPV	N/MIPPV

<sup>a</sup>Motor levels.

<sup>b</sup>Adequate neck function involves sufficient oral and neck muscular control to rotate, flex, and extend the neck to grab and use a mouthpiece for IPPV; adequate bulbar function to prevent aspiration of saliva to the degree that the SpO<sub>2</sub> baseline decreases below 95%.

EPR, electrophrenic pacing; IAPV, intermittent abdominal pressure ventilator; MIPPV, mouthpiece intermittent positive pressure ventilation; NIPPV, nasal intermittent positive pressure ventilation; TIPPV, tracheostomy intermittent positive pressure ventilation.

### Oximetry Monitoring and Feedback Protocol

For a patient with chronic alveolar hypoventilation who has not been using ventilatory support, or the patient being weaned from tracheostomy IPPV, introduction to and use of mouthpiece or nasal IPPV is facilitated by oximetry feedback. An SpO<sub>2</sub> alarm may be set from 93% to 94%. The patient sees that by taking slightly deeper breaths, SpO<sub>2</sub> will exceed 95% within seconds. He or she is instructed to maintain SpO<sub>2</sub> above 94% all day (232). This can be achieved by unassisted breathing for a period of time, and once tiring, by mouthpiece or nasal IPPV. With time, the patient requires increasing periods of IPPV to maintain adequate ventilation (SpO<sub>2</sub> >94%). In this manner, an oximeter may also help to reset central ventilatory drive.

Oximetry feedback is especially important during the management of respiratory tract infections. The cough of infants and small children who can never sit is inadequate to prevent chest cold–triggered pneumonia and respiratory failure. Children who can sit are usually protected from this until after 2 years of age. Older children and adults whose assisted CPF decrease below 300 L/m are also at high risk for chest cold–triggered ARF. Such patients require continuous SpO<sub>2</sub> monitoring and are taught that any dip in SpO<sub>2</sub> below 95% is due either to underventilation, or bronchial mucous plugging, and if these two causes are not quickly addressed, may lead to atelectasis or pneumonia. They are instructed to use noninvasive IPPV to maintain normal ventilation and manually or mechanically assisted coughing to reverse mucous plug associated oxyhemoglobin desaturations. In this way, most episodes that would otherwise cause ARF are successfully managed at home.

For adults with infrequent chest colds, rapid access to this equipment may be all that is necessary. Likewise, with intact bulbar muscle function, manually assisted coughing may be sufficient to generate effective cough flows, whereas with complete bulbar muscle paralysis, even MAC may not spare patients from respiratory failure.

### Treatment of Sleep-Disordered Breathing

Significant weight reduction can improve the central and obstructive apneas and hypopneas of sleep-disordered breathing in the morbidly obese (244). CPAP can be effective for patients with primarily obstructive events, but it is not adequate for those who have restricted pulmonary volumes and hypercapnia. Mask discomfort and air leakage into the eyes can make the use of CPAP via CPAP masks intolerable for about 35% of patients (245).

Independently varying inspiratory positive airway pressures (IPAP) and expiratory positive airway pressures (EPAP) with BiPAP machines can be effective for hypercapnic patients. The greater the pulse pressure difference—that is, the difference between the IPAP and EPAP—the greater the inspiratory muscle assistance. Often, 20 to 30 cm H<sub>2</sub>O IPAP and minimum EPAP are most effective. Portable volume ventilators are used instead of BiPAP to deliver nasal IPPV for hypercapnic

morbidly obese patients who require greater inspiratory muscle assist at higher peak ventilator pressures than can be provided by BiPAP.

Another convenient long-term solution, effective for many obstructive sleep apnea syndrome patients, is the use of an orthodontic splint that brings the mandible and tongue forward, thus, helping to splint open the hypopharynx (246). Uvulopalatopharyngoplasty and mandibular advancement procedures have also been used but are usually ineffective (247–249).

### Invasive Ventilatory Support

The use of noninvasive aids can be contraindicated by the presence of any of the following: saliva aspiration causing SpO<sub>2</sub> to remain below 95%, depressed cognitive function, orthopedic conditions interfering with the application of noninvasive IPPV interfaces and exsufflation techniques, pulmonary disease necessitating high FiO<sub>2</sub>, or uncontrolled seizures, or substance abuse (245,250). Also, the presence of a nasogastric tube can hamper the fitting of a nasal interface and the use of mouthpiece or nasal IPPV by interfering with both soft palate closure of the pharynx and seal at the nose. Although tracheostomy IPPV can extend survival for patients with neuromuscular ventilatory failure (251), morbidity and mortality outcomes are not as favorable as by noninvasive approaches (195). Tracheotomy is indicated for severe bulbar ALS patients (199), rarely if ever for DMD patients (252), and rarely for SMA patients. It has been found that even SMA type 1 children can have less long-term morbidity when managed without tracheostomy tubes (205). Patients with DMD, even those who are continuously ventilator dependent on noninvasive IPPV, can avoid hospitalizations and pulmonary morbidity and mortality for decades, and tracheotomy indefinitely when properly managed by using respiratory muscle aids (252).

Although widely thought to be fatal before age 2, management of SMA1 according to a recently described noninvasive respiratory aid protocol has thus far allowed many of these patients to survive age 15 without a tracheostomy. Of 47 patients, 32 used high-span BiPAP only during sleep; 6 required it over 16 h/d and become hypercapnic and dyspneic when not using it; and 9 required it continuously with little or no breathing tolerance (253).

Considering the eight deceased NIV patients, three died suddenly at home from bradycardias. One died from an intracranial hemorrhage. Two died from mucus plugs during upper respiratory infections when intubation was unsuccessful; one from septic shock; and one from pulmonary embolism. Of the 32 patients who used high-span BiPAP only during sleep, 10 were able to speak clearly, 16 had severe dysarthria, and 6 were a verbal. Of the six 16 to 20 h/d users, 5 had severe dysarthria and 1 was a verbal. Of the 9 who require continuous support, 1 could speak clearly, 2 had severe dysarthria, and 6 were a verbal. Thus, 34 of the 47 NIV users could communicate verbally in contrast to 6 of the 27 with tracheostomy tubes.

When tracheostomy IPPV is used despite the fact that oropharyngeal muscles are sufficient for swallowing, speaking, and permitting decannulation to NIV, either cuffless tubes or tracheostomy cuff deflation should be used up to 24 hours a day (101). Delivered air volumes are increased to compensate leak and support speech and one-way valves used to further facilitate verbal communication (98). Tracheostomy buttons are useful to optimize air passage through the upper airway for autonomous breathing as well as during transition from tracheostomy to noninvasive IPPV (239).

### Quality of Life

Misconceptions about the undesirability of “going on a respirator” have far-reaching negative effects for persons now happily being supported on a respirator, and mitigate the positive effects it could have for some types of chronically impaired persons whose quality of life also could be enhanced by the use of a ventilator (254). Although it would seem that intelligent, self-directed individuals should be fully informed about therapeutic options, in the frenzy of seeking a less expensive health care delivery system, some physicians have suggested eliminating the patient from the decision-making process. As recently as 1989, it has been recommended that a physician’s assessment of patients’ quality of life be done “independent of the patient’s feelings” to guide the clinician in whether to institute mechanical ventilation (255).

Poor quality of life is usually given as the reason for withholding ventilator use (256). However, no quality-of-life criteria can be appropriately applied to all individuals. Life satisfaction depends, rather, on personal preferences (257) and on subjective satisfaction in physical, mental, and social situations, even though these may be deficient in some manner. Thus, not quality of life but potential satisfaction with life should be considered. It is particularly appropriate that the life satisfaction of individuals who are living the consequences of having chosen to use ventilators be considered when deciding about such ethically and financially complex matters as ventilator use for others. Interestingly, data indicate that severely disabled, long-term postpoliomyelitis, DMD, and SCI ventilator users (256) generally have very positive views of their lives and life satisfaction. These individuals find quality of life in interpersonal activities, and they are very significantly more satisfied with life than health care professional estimates suggest (257). Crucial for this is often the availability of personal attendant-care services. Thus, in the face of calls to limit entitlement spending, it should be noted that a society willing to provide free room, board, health care, legal and educational services, vocational training, and cable television for felons at exorbitant cost has the ethical responsibility to provide attendant-care services to those in need, some of whom are crime victims themselves. Our specialty needs to do more than instruct the patient and his/her family; it must advocate for them to assure that they have access to appropriate community resources.

# Burn Rehabilitation

## INTRODUCTION

Burn injuries pose complex physical and psychological rehabilitation challenges. The incidence of burns has decreased dramatically in the past 50 years as a result of public education and home and work safety efforts. Additionally, survival after burn injury has increased significantly in the same time period (1). Advances in the field that have contributed to survival include the formation of specialized burn centers, early excision and grafting, improved resuscitation and intensive care, and the development of topical and systemic antibiotics (1,2). With dramatic improvements in survival, the focus of burn care is increasingly shifting toward rehabilitation. Burn survivors have complicated rehabilitation needs including scarring, contractures, pain, amputations, neurologic injuries, psychological problems, and community integration issues. The period of rehabilitation may last from months to many years after injury. The physiatrist is an integral member of the burn care team from the time of injury to long-term follow-up.

## EPIDEMIOLOGY

It is estimated that 1.25 million people experience burn injuries each year. Of those, approximately 500,000 receive some form of medical treatment and 40,000 are hospitalized (3,4). Burns predominantly affect young men (mode age: 20 to 40; male: 70%). Two thirds of burn injuries affect adults and one-third affect children. Most burns occur by fire/flame (43%) or scald injuries (36%) (Fig. 43-1). Other etiologies that comprise the minority of burns include electrical, contact, chemical, tar, radiation, and grease injuries as well as skin diseases. Approximately one third of burn injuries are associated with concomitant alcohol or drug use. A large majority of burn survivors have less than or equal to a high-school education (82%). Most injuries (65%) are result of an accident that is not work related. A minority of burn injuries (17%) occur at work.

Approximately 5% of burn injuries are the result of child abuse or adult assault or abuse. Among children less than 2 years old, burn injuries represent the most common cause of accidental death; most of these deaths are a result of abuse. Overall, the survival rate is approximately 95%. The risk of death is increased for those at the extremes of age, with inhalation injury and with larger burns (5–7).

## PATHOPHYSIOLOGY

### Normal Skin

The skin is the largest organ of the body. It serves multiple functions; it acts as a protective barrier to the external environment, regulates temperature and fluid homeostasis, plays a key role in sensation, and contributes to our sense of identity and communication. Skin is a complex organ composed of two layers, the epidermis and dermis (Fig. 43-2).

The outermost epidermis consists of stratified squamous epithelium. This layer contains no blood vessels and the cells are nourished by diffusion from capillaries in the upper layers of the dermis. Cells are formed through mitosis at the basal layer (stratum basale). In addition to forming the bottom layer of the epidermis, the stratum basale lines the hair follicles and sweat glands. (Hair follicles and sweat glands are a source of epidermal cells that enable partial thickness burn injuries to heal spontaneously.) The mitotic daughter cells migrate toward the surface changing shape and composition as they die due to isolation from their blood source. The cytoplasm is released and the protein keratin is inserted. They eventually reach the outer layer and desquamate. This process is called keratinization and takes approximately 30 days. This keratinized layer of skin (stratum corneum) is responsible for keeping water in the body and keeping harmful chemicals and pathogens outside the body, making skin a natural protective barrier.

The dermis resides beneath the epidermis and consists of a vascular connective tissue that supports and provides nutrition to the epidermis and skin appendages. The dermis contains nerve endings, capillaries, lymphatic vessels as well as appendages that include hair follicles, sweat glands, and sebaceous glands. The eccrine sweat glands release heat from the body's surface through sweat, thereby contributing to thermoregulation. The sebaceous glands secrete an oily substance called sebum that protects the skin and hair and moisturizes the skin.

### Classification of Burn Injury

One of the most common classification systems uses depth of injury to categorize the severity of the burn. Superficial injuries, previously termed first-degree burns, solely affect the epidermis. The category of second-degree burns is now divided into superficial and deep partial thickness burns. The former interrupt the epidermis and superficial dermis and present with blistering, moist and painful skin that blanches with

**FIGURE 43-1.** Scald injury. Note the splash marks and irregular depth of burns.

pressure. The latter involve the epidermis and deep dermis, including skin appendages, affecting some degree of sensory and sweat gland function. Deep partial thickness burns present with a dry or waxy appearance and are less painful than more superficial burns. Full thickness burns, formerly third-degree burns, affect the entire epidermal and dermal layers and result in complete loss of skin appendages. They present as white waxy to leathery gray to charred black appearance, are insensate to pain, and do not blanch to pressure. Deep injuries may affect muscle, tendon, and bone. Such deep injuries are not part of the newer classification system, but were previously classified as fourth-degree burns (see Fig. 43-2; Table 43-1).

Burn injuries are also classified by size. Lund and Browder (8) diagrams provide a systematic method for calculating total body surface area (TBSA) burned for both adults and children. In contrast to an adult, a child's head represents proportionally more and their legs represent proportionally less of their body

**FIGURE 43-2.** Diagram of normal skin histology with depth of burn injury indicated. Note the layers, epidermis and dermis, and skin appendages. (From Kucan JO. Burn and trauma. In: Ruberg RL, Smith DJ Jr, eds. *Plastic Surgery: A Core Curriculum*. St. Louis, MO: Mosby-Year Book; 1994:212.)

surface area (Fig. 43-3). The rule of nines is used clinically as a quick estimate of TBSA (Fig. 43-4).

Many burn injuries are best treated in specialized burn centers. The American Burn Association in consultation with the American College of Surgeons has developed clinical criteria for referral to a burn center (9) (Table 43-2).

**TABLE 43.1** Burn Severity Classifications

Old Classification	New Classification	Appearance/Symptoms	Course/Treatment
First degree (epidermis)	Superficial thickness	Erythematous, dry, mildly swollen, blanches with pressure, painful	Exfoliation, heals spontaneously in 1 wk, no scarring
Second degree (dermis)	Superficial partial thickness	Blistering, moist, weeping, blanches with pressure, painful	Reepithelialization in 7–20 d
	Deep partial thickness	No blisters, wet or waxy dry, variable color, less painful, at risk for conversion to full thickness because of marginal blood supply	Reepithelialization weeks to months. Skin grafting may speed recovery. Associated with scarring
Third degree (all of dermis and epidermis)	Full thickness	White waxy to leathery gray to charred black, insensate to pain, does not blanch to pressure	Reepithelialization does not occur, requires skin grafting, associated with scarring
Fourth degree (extends to muscle bone, tendon)	N/A	Black (eschar), exposed bones, ligaments, tendons	May require amputation or extensive deep debridement

**FIGURE 43-3.** Lund and Browder diagram. (From Artz CP, Moncrief JA, Pruitt BA. *Burns: A Team Approach*. Philadelphia, PA: Saunders; 1979.)

### Effects of Thermal Injury

In thermal injury, the extent of tissue damage is related to the location, duration, and intensity (temperature) of heat exposure. Also of significance, those at the extremes of age have fewer protective layers of epithelium; therefore the same location, duration, and intensity of heat will produce a more serious burn injury in children and elderly than in other adults.

After burn injury a cascade of physiologic processes affect the thermal injuries ultimate impact. There is a complex interplay of local and circulating mediators, including histamine, prostaglandins, thromboxane, kinins, serotonin, catecholamines, oxygen free radicals, platelet aggregation factors, angiotensin II, and vasopressin. Initially, there is vasoconstriction at the site of injury mediated by release of norepinephrine and serotonin. A few hours after injury vasoconstriction turns to vasodilation, increased capillary permeability, and leakage of plasma into the extravascular space. Histamine is released. Damaged cells swell. Fluid shifts result in increased extravascular edema and intravascular hypovolemia. Platelets and leukocytes aggregate, leading to thrombotic ischemia (10,11). In severe burn injuries, inflammatory mediators are released and compromise cardiovascular function. Burn shock ensues, resulting in decreased intravascular volume, increased systemic vascular resistance, decreased cardiac output, end-organ ischemia,

**FIGURE 43-4.** The rule of nines is used to estimate the percent of body surface area burned. (From Artz CP, Moncrief JA, Pruitt BA. *Burns: A Team Approach*. Philadelphia, PA: Saunders; 1979.)

and metabolic acidosis. Resuscitation treatment helps reverse this potentially deadly cascade.

Damaged skin results in impairment in most major functions of the integumentary system. In areas of burn injury, skin loses its ability to act as a protective barrier and homeostatic regulator. This may lead to significant losses of body fluid, impaired thermoregulation, and increased susceptibility to infection. In large burns, loss of fluid by evaporation contributes to the development of hypovolemia and shock.

**TABLE 43.2 American Burn Association Criteria for Referral to a Burn Center**

Partial-thickness burn greater than 10% TBSA
Burns that involve the face, hands, feet, genitalia, perineum, or major joints
Any full-thickness burn
Electrical burns, including lightning injury
Chemical burns
Inhalation injury
Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality
Any patient with burn injury and concomitant trauma in which the burn injury poses the greatest risk of morbidity and mortality
Burned children in hospital without qualified personnel or equipment for the care of children
Burn injury in patients who will require special social, emotional, or rehabilitative intervention

Release of catecholemines plays a key role in the development of a catabolic state after burn injury. Tachycardia, increased nutritional demand and weight loss typically ensue. Gastric dilation and gastrointestinal ileus are common in the first few days after burn injury. Also, immune function is impaired. The arachidonic acid and cytokine cascades alter the function of lymphocytes, macrophages, and neutrophils. As a result, patients are at increased risk of infection. Inhalation injury is commonly associated with fire injuries. Noxious gaseous components of smoke directly damage the respiratory tract. Patients are at risk for carbon monoxide intoxication, upper airway edema and obstruction, pneumonia, and dependence on mechanical ventilation (11,12).

### Skin Regeneration and Scarring

Spontaneous reepithelialization is impossible with a full-thickness burn injury because of destruction of the dermal appendages. Full-thickness burns result in hair loss, sensory impairment, loss of normal skin lubrication, and heat intolerance because of destruction of sweat glands.

Healing and regeneration of skin in partial-thickness burns arise from the epithelial linings of the hair follicles and sweat glands (stratum basale). Depending on the depth, healing is completed within 14 to 21 days. The new skin again functions as a temperature regulator and a protective barrier against bacteria. After epithelialization there is continued healing with regeneration of the peripheral nerves, sometimes associated with symptoms of neuropathic pain and itching. Although epithelium covers the wound, dermal scarring occurs in the burn wound on a continuous basis for several months after injury. The healing process is ongoing from 6 months to 2 years until the skin is mature. By that point the vascularity of the wound has returned to near normal, and there is no further collagen deposition in the wound.

## ACUTE MEDICAL MANAGEMENT

### Acute Care of Burn Wounds

While the long-term goals of burn wound care are to restore skin integrity, function, and appearance, the immediate goals post resuscitation are to prevent infection, decrease pain, prepare wounds for grafting, prevent contracture and scarring, and maintain strength and function.

Debridement, the removal of eschar and necrotic tissue, prepares a viable base for wound healing and grafting. Eschar is a composite of coagulum and other tissue debris. Like necrotic tissue, eschar provides an excellent environment for bacterial growth. Since eschar has no microcirculation, bacterial invasion cannot be resolved with systemic antibiotics.

Debridement is performed by several methods. Water immersion, water spray, and wet to dry dressing are examples of mechanical debridement. Commercially available topical enzymes are available for debridement and include substances such as sutilains that induce proteolysis, fibrinolysis, and collagenolysis.

There are different types of surgical debridement. Sequential, also called tangential, debridement is the process of removing

thin slices of necrotic tissue. Tissue is removed until a viable tissue bed is reached. Fascial debridement surgically removes tissue down to fascia. In this type, a viable wound bed is assured but a significant soft-tissue defect results. Circumferential fascial debridement places patients at high risk for chronic edema.

Deep skin burns are inelastic and the injured skin does not accommodate to the massive edema associated with acute burn injury. In a circumferential burn, the inelastic tissue acts as a tourniquet. The tourniquet effect can lead to a compartment syndrome, defined as compartmental pressure of at least 40 mm Hg. If this occurs, escharotomy is indicated. Escharotomy, surgical decompression of the compartment, is urgently performed to avoid necrosis of the underlying tissues that results from sustained elevated pressure. Escharotomy incisions are performed along the medial and lateral aspects of the extremity. This procedure is critical in situations involving full-thickness circumferential injuries of the chest, arms, or legs. If escharotomy does not successfully reduce the elevated pressure, a fasciotomy is indicated.

### Grafting

The introduction of early excision and grafting in the last 40 years has contributed significantly to decreased length of hospitalization as well as improved survival rates, cosmesis, and functional outcome.

Homografts, tissue taken from one's own species, include cadaveric tissue and human fetal membranes. Heterografts, also known as xenografts, are tissues taken from nonhuman species that are used as human grafts. These biological tissues, most commonly porcine tissues, provide wound closure, modulate metabolic needs, and reduce evaporative fluid. These temporary grafts also act as a mechanical barrier to infection and aid pain relief. Temporary grafts are useful as "test grafts" to determine if the wound bed will accept an autograft. Typically, homografts and heterografts are removed or replaced after several days because the patient's immune system rejects them. It is not routine to use immunosuppressant therapy in conjunction with grafting.

Synthetic wound dressings are available, including polyvinylchloride, polyurethanes, and other plastic membranes. They are vapor and gas permeable. Such grafts are employed until autografting is feasible or the wound heals. Bilaminate analogs composed of thin sheets of silastic as well as epidermal and dermal components are available. Biobrane and Integra are the two most common biosynthetic dressings.

In the world of skin substitutes and biologic dressings, autografts are the gold standard. The bioengineered substitutes can be used as a temporary covering prior to autografting, or as a neodermal base on which the autograft is placed.

Pham, in a recent evidence-based literature review of bioengineered skin substitutes, concluded that Biobrane, TransCyte, Dermagraft, and allogeneic cultured skin are at least as safe and effective as other wound dressings or allografts for partial thickness wounds. The authors concluded that Integra is best used for smaller burns; evidence suggests that burns of 45% or greater experienced higher infection rates. TransCyte provides good coverage in areas of high contour such as the face (13).

**FIGURE 43-5.** Harvesting donor site for autologous skin graft.

Autografts are harvested from the patient's own skin. In this process, skin is surgically removed from one's own body and is relocated to another site (grafted) (Figs. 43-5 and 43-6). Autografts are placed on a wound bed clean of any nonvital tissue or debris and without evidence of infection.

Split thickness grafts are applied in sheets or may be meshed prior to application. Cutting small regularly staggered parallel slits in the sheet of harvested skin creates a meshed skin graft. This expands the size of the graft to several times its original surface area. Meshed grafts are less cosmetic than full-thickness grafts. Meshed grafts heal quickly, and the epithelialization that occurs in the interstices creates a meshlike appearance to the healed skin (Fig. 43-7).

Full-thickness skin grafts are not meshed and result in a more cosmetic appearance. They are typically applied to cosmetically critical areas such as the face, neck, and hands. In addition, full-thickness grafts are used almost exclusively in reconstructive surgery.

## Dysphagia

Dysphagia is a common problem with large burn injuries and complicates the delivery of adequate nutrition for healing and recovery. Burn induced hypermetabolism increases the caloric

**FIGURE 43-6.** Healing donor sites.

**FIGURE 43-7.** Split-thickness skin grafts used to close wounds of residual limb after amputation.

needs of the patient. Weakness, inhalation injury, tracheostomy, medication, oral motor dysfunction, and multiple other factors contribute to the development of dysphagia. Tracheostomy is associated with aspiration, pneumonia, and the development of tracheal-esophageal fistulae. Vocal cord paresis is associated with inhalation injury and endotracheal intubation.

Vigilant monitoring is required to recognize dysphagia early and prevent aspiration and associated morbidity. Edelman et al. (14) demonstrated the importance of evaluating patients swallowing function.

In this study, dysphagia was initially assessed by bedside swallowing evaluation, and, if abnormal, followed by modified barium swallow examination. They found that oral phase dysphagia is usually due to impaired range of motion (ROM), weak mastication, and impaired oral seal from burn wounds or scar formation. Esophageal dysfunction is a secondary complication of intubation or tracheostomy. Pharyngeal phase dysphagia is usually a result of inhalation injury, complications of tracheostomy, intubation, or burn scar. Pharyngeal dysphagia is associated with the highest risk of aspiration.

Interventions include evaluating endotracheal tube position, size, and location. Selection of appropriate food consistency and positioning, including head and neck positioning, are successful measures to reduce the risk of aspiration.

## REHABILITATION

Restoration of independent function is the ultimate goal of rehabilitation. Functional restoration includes all aspects of the human life such as strength, ROM, mobility and self-care, reintegration into family and community, adaptive psychosocial responses, and self-determination.

Rehabilitation after a severe burn injury is a multi-stage process that may take years. Acute rehabilitation goals include interventions to facilitate wound healing, achieve pain

control, prevent joint contracture and weakness, and promote independent mobility and activities of daily living (ADL). Details of the injury, age, premorbid functional level, and health are determinants of an individual's rehabilitation plan. Therapy is individualized according to burn location, depth, and size as well as other associated injuries or complications. Successful rehabilitation involves multiple disciplines working collaboratively with the patient to achieve the highest level of functioning possible.

### Positioning

Contractures are a common complication of deep partial and full-thickness burn injuries. Proper positioning is a basic tenet of contracture prevention. Proper positioning also helps prevent other complications such as pressure ulcers and compression neuropathies (Fig. 43-8; Table 43-3).

Contracture prevention is based on the principle of tissue elongation. Patients often prefer to position injured tissue in a shortened, nonstretched state for comfort. Typically, this is a position of flexion and adduction. Such positions of comfort lead to contracture. Positions of extension and abduction are usually indicated to counter the position of comfort. One must prescribe positioning in accord with the location of the injury and direction of the contracture. Joints with overlying deep burns are placed in a position of tissue elongation. For example, a deep burn of the elbow is kept in extension to avoid a flexion contracture that would impede reaching.

Contractures are not limited to joints. Other areas, such as the soft tissue of the lips and mouth, require stretching,

exercise, and therapeutic devices to maintain tissue length and function.

### Splinting

Splints are commonly employed for burn injuries. These devices provide multiple functions including facilitating proper positioning, preventing joint contractures, protecting skin grafts or fragile wounds, or assisting desired motion.

Splints are fabricated from many materials. Low-temperature thermoplastic orthotics are most common. Low-temperature plastics have several advantages including the ability to be warmed at the bedside in heated water and fitted to the patient immediately. These plastics are conformable at low temperatures and therefore can be readily remodeled and adjusted as needed in the clinic or at bedside.

Custom splints can be designed for virtually all parts of the body. Hand injuries commonly require custom splints. Custom splints are advantageous for difficult to fit areas and for sites that require unique design or built-in features, such as facilitating motion at a single joint. They are costly, require experienced staff for construction and maintenance, and necessitate that materials are available on site for fabrication.

Commercially available prefabricated splints may be cost-effective; however, these splints often require modification to fit properly or to achieve the intended purpose. Some clinicians believe that the commercially available prefabricated splints are best used for positioning the knee and ankle. Splints that are simple and straightforward in design and function are "user friendly." Such splints are more likely to be applied correctly and compliantly. An incorrectly applied splint can lead to further injury, including nerve damage, loss of skin graft, and other skin trauma. A properly designed and fitted splint avoids pressure over bony prominences and is compatible with wound dressings and topical medications. It is often desirable to fabricate the splint with moldable materials that can be modified as a patient's needs change.

The basic rule of splinting is to splint the body part in a position opposite of the expected deformity. Factors to consider when prescribing a splint include burn size, burn location, burn type, functional goals, and patient activity level.

The wearing schedule for splints is individualized. In the case of the comatose patient, splints should be worn for 2 to 4 hours and then removed for a similar length of time and then reapplied. The wearing schedule can be modified as the patient's level of participation is increased. Splints may be worn to maintain the gains made in therapy.

If normal ROM of a joint is preserved, a splint is not indicated unless a joint or tendon is exposed or the patient is noncompliant with positioning. Common splints include the knee extension splint to prevent knee flexion contracture and posterior foot drop splint to maintain neutral ankle positioning.

The upper extremity is the most common site for contractures. For axillary burns, an "airplane" splint is used to prevent shoulder adduction contracture. An "airplane" splint holds the upper extremity in approximately 15 degrees of horizontal adduction

**FIGURE 43-8.** Therapeutic positioning to prevent contracture formation. (From Helm PA, Kevorkian CG, Lushbaugh M, et al. Burn injury: rehabilitation management in 1982. *Arch Phys Med Rehabil.* 1982;63:8.)

**TABLE 43.3** Proper Positioning for Preservation of Function in Acute Burns

Joint/Body Region	Preferred Position	Positioning Devices
<b>Upper Extremity and Trunk</b>		
Neck	Slight extension	Neck collar Splint that conforms to the neck No pillows under the head
Axillae	Horizontal adduction 15 degrees Abduction 80 degrees	Airplane splint Wedge to positioning to abduction If rest of upper extremity involved Can support UEs: Bedside table Side boards/bedside extensions
Elbow	Extension 5 degrees	Arm trough splint Elbow extension splint
Forearm	Supination	Arm trough
Wrist	Neutral or slight extension	Wrist cock-up splint Part of resting hand splint
Hand	I, P joints: full extension MCP: 70–80 degrees flexion Abducted from palm Thumb opposition	Resting hand splint  Soft web spacers Intrinsic plus hand splint C bar for thumb
Chest and trunk	Neutral with level hips	Figure of eight device to reduce protraction
<b>Lower Extremity and Trunk</b>		
Hip	Neutral extension Abduction 20 degrees	Wide soft straps to avoid frog leg position especially in children
Knee	Extension	Knee extension splint; immobilizer
Ankle	90 degrees That is neutral Dorsiflexion, plantar flexion Inversion/eversion	Posterior shell with ankle in neutral L/Nard; PRAFO-like devices
Foot	Neutral forefoot Supination/pronation; toes extended	

and 90 degrees of abduction. This splint prevents shortening of the anterior and posterior axillary folds. Modifications or inserts are used to maintain the contours of the axillary apex and increase ROM as tolerated (Fig. 43-9). In injuries of other upper-extremity joints, splints are fabricated to meet the specific positioning demands of the elbow, forearm, and wrist.

To correct a contracture various static progressive splints or orthoses are designed to provide a slow progressive sustained stretch. The literature documents success using serial casting to achieve contracture correction as well (15). Staley and Serghiou (16) summarized serial casting use in burn injury:

- Long duration of stretch with minimal force.
- Protection of exposed tendons
- Mechanical forces to remodel scar
- Cost-effective
- Treatment useful in children and noncompliant patients
- Treatment option when an open wound is present.

Splints are also valuable in the postacute period to prevent contractures until the tissue length is stabilized, after surgical release of a contracture, or after skin grafting.

## Hands

Hands require special attention. When evaluating the burned hand, individual joint motion should be assessed. Limitations in ROM results from decreased tendon sliding, decreased muscle strength, tendon shortening, skin/muscle/ligament/tendon tightness, joint restriction, or a combination of these processes.

During the acute phase, the hands are positioned and splinted to prevent shortening of the joint capsules, collateral ligaments, and muscle tendons. Edema can complicate care as it accentuates metacarpophalangeal (MCP) joint extension and interphalangeal (IP) joint flexion. The resulting combination of MCP hyperextension and IP joint flexion produces the intrinsic minus deformity of the hand, also called claw hand.

The hand is splinted with the wrist in slight extension, the MCP joints in 70 to 80 degrees flexion, IP joints in extension, and the thumb abducted from the palm. Fingers are positioned in abduction (Fig. 43-10). If the burns are limited to the palmar aspect, then the MCP and IP joints are positioned in extension, fingers abducted, and the thumb abducted from the palm. Palmar splints may need modifications to maintain the palmar arch. Elastic wraps or straps are employed to secure the splint. Elastic wraps are applied in a figure of eight formation to avoid circumferential constriction. Straps should be soft and applied in a crisscross orientation.

Circumferential hand burns often damage the web spaces of the hand. Preservation of the web spaces is important for hand rehabilitation. For example, loss or shortening of the first web impairs thumb opposition and abduction and interferes with grasp (17). Early intervention is critical. In addition to abduction, exercise to all the digits, web space dressings, and soft inserts or straps are placed in the web spaces. Also, thermoplastic inserts may be customized and fitted in these areas. Compression gloves may be used in conjunction with the splints. In mild cases, compression gloves may be sufficient to preserve web spaces and function.

**FIGURE 43-10.** Resting hand splint.

Exposed tendons require splinting in a slack position. The tendon should be kept moist to avoid desiccation and denaturation. With time, the tendon may revascularize and become functional. If the exposed extensor hood of the fingers is not kept slack, the central slip can fail and lead to a boutonniere deformity. In cases of extensor hood rupture, the finger is positioned in extension. In approximately 6 weeks, scar tissue may form to bridge the extensor surface and act as a functional substitute. After that time, active ROM can be initiated (18).

For exposed joints, a splint is prescribed to provide protection. Gentle ROM is performed to maintain motion. If the joint capsule is violated, the joint is at risk for ankylosis. In such cases, the joint is best placed in a function position.

Edema can cause a claw hand. After 12 to 18 hours, edema changes consistency to a gelatinous substance secondary to lymphatic vessel occlusion and impaired fluid clearance. This gellike quality makes the edema more difficult to resolve. In the acute stage after injury, the upper extremity and hand are typically suspended above the patient's head to aid fluid return and reduce edema. Care is taken not to stretch the brachial plexus or damage the ulnar nerve.

The resting hand splint, with the inclusion of wrist extension, contributes to edema control of the hand (see Fig. 43-10). This splint stretches the normally redundant dorsal skin, thereby limiting space for edema collection. Edema formation coupled with the flexor tendon pull increases flexion at the IP joints resulting in a claw hand deformity.

Once skin closure is achieved, a compression glove is prescribed to assist with edema control (Fig. 43-11). Passive exercise and scar suppression are also employed to assure restoration and maintenance of normal ROM.

## Exercise

In burn rehabilitation, one of the earliest goals of exercise is to maintain or achieve normal ROM. For the obtunded or comatose patient, passive ROM exercises emphasizing the end ROM is appropriate. Alert and cooperative patients can participate in active and active-assisted exercise. With children, developmentally appropriate exercise and play activities are indicated to achieve the therapy goals.

Surgical anesthesia can provide an opportunity to perform ROM exercises and determine objective measurements of

**FIGURE 43-11.** Compression gloves for hypertrophic scar suppression.

range. In this setting, one can perform ROM without concern for pain. The opportunity to assess ROM under anesthesia is valuable in the case of a child, an uncooperative patient, or if pain is inhibiting ROM exercise.

Stretching exercises are prescribed when ROM is abnormal. The biomechanics of skin and muscle are different; therefore, the two tissues are stretched differently. Stretching of injured skin or scar tissue requires a slow sustained mechanical stretch to enhance elongation of collagen and underlying fibers. When a prolonged stretch is performed, the stretch is maintained until the tissue blanches. Blanching indicates that the tissue is near its yield point, the point at which the skin is at risk of tearing (19,20).

After burn injury, muscular weakness, fatigue, and deconditioning are serious problems. These sequelae interfere with function, such as ambulation, ADL skills, and endurance. Loss of muscle mass and, in children, the additional loss of bone mass, interfere with the restoration of function, return to work or school (21,22).

Literature indicates that a structured exercise program composed of aerobic and resistance training leads to increased function as measured by increased muscle mass, strength, and cardiovascular endurance (23). Suman and Herndon (24) demonstrated the efficacy of a supervised exercise program for children, ages 7 to 18 years, that included resistance and aerobic exercise. His team trained children in eight basic exercises, including bench press, leg press, and triceps curls under the supervision of a physical therapist in an outpatient setting. The control group was instructed in a home exercise program. The participants of the supervised resistance and aerobic program required significantly fewer surgical releases up to 2 years after the intervention (25). Suman et al. (26) also demonstrated that children had increased lean body mass and muscle strength with structured exercise and the concurrent administration of the anabolic steroid, oxandrolone, for 1 year after injury. Anabolic agents, such as oxandrolone and human growth hormone, have been demonstrated to reduce the effects of hypermetabolism while also increasing muscle mass and strength and decreasing resting energy expenditure in children and adults (27–31).

St-Pierre et al. (32) demonstrated that individuals with small burns did not differ from those without injury in muscle strength. However, for those with greater than 30% TBSA burn produced less torque, work, and power in their quadriceps when compared to matched controls. de Lateur et al. (33) reported that a structured aerobic exercise program, consisting of three times a week aerobic treadmill training for 12 weeks combined with a standard burn therapy program, achieved improved aerobic capacity. This literature suggests that regular exercise after burn injury, like in other adults, results in improved flexibility, endurance, balance, and strength. Such gains are important for returning to full independence and function. Other likely benefits are reduced anxiety and an improved sense of well-being (34).

### Gait

Independent walking may be the single most important factor in determining discharge disposition after severe burn injury.

Farrell et al. (35) found that independent ambulation predicted discharge from the acute burn unit to home.
